ON THE DIAGNOSTIC AND PROGNOSTIC VALUE OF TENDON REFLEXES.

BY JOHN FERGUSON, M.A., M.D. TOR., L.R.C.P. EDIN.,

DEMONSTRATOR OF ANATOMY, WINTER SESSION; LECTURER ON NERVOUS DISEASES POST-GRADUATE COURSE, AND IN THE SUMMER SESSION, MEDICAL COLLEGE, UNIVERSITY OF TORONTO.

IT would be an interesting and important task to trace the growth of our knowledge on the knee jerk, the knee phenomenon, or the patellar tendon reflex. This, however, is not the purpose of this article. I propose confining my observations entirely to those aspects of the knee-jerk that are of a diagnostic or prognostic value. Incidental mention shall be made of the foot, or ankle clonus, and other tendon reflexes; but, as the phenomena of the deep reflexes can be best studied in the knee-jerk, this shall receive the greatest share of attention.

The physiology of the tendon reflexes has been and is still much disputed. Erb, Joffroy, Schultze, Brissaud, Gowers, and others hold that they are of a reflex character and of spinal origin; while, on the other hand, Waller, Westphal, Zichen, and others hold that they are due to a mechanical excitation of the muscle, caused by a blow upon its tendon. When, however, these two views are closely examined, there is not such a wide difference as at first sight might appear to be the case. Those who hold that the patellar reflex is due to the mechanical excitation of the muscle admit that the state of muscular irritability which causes the muscle to respond to the percussion on the tendon is in turn due to a nerve-stimulus supplied to it from the spinal cord. Thus it will be seen that there is not such a wide gulf separating the two sets of observers. My own view of the tendon reflexes, as expressed in the New York MEDICAL RECORD, of November 28, 1891, on the subject of the knee-jerk, and in the *Alienist and Neurologist*, of January, 1892, on some cases of hemiplegia, is in accord with those of Bastian, Bowlby, and Jackson, that the tone of the muscle is due to its normal and healthy connection to the spinal centre; and this latter receives its stimulus from the cerebellum, the cerebellar influx, and is held in check by the cerebrum, the cerebral inhibition. The derangement of this dynamic apparatus would at once derange the mechanism of the tendon reflexes, and there would result either a deficiency, an exaggeration, or an abolition of them. Such derangement might be of general or local origin. Gowers's view that there is a condition of muscle-tone maintained by the spinal centres, and that the tension, suddenly added to the muscle-fibres by the blow upon the tendon, causes these fibres to respond at once by contracting, is no doubt correct. While this is true, I hope to show that these spinal centres are in turn under the cerebral and cerebellar control, as above mentioned.

When the control of the cerebrum is removed by the occurrence of a hemorrhage, the growth of a tumor, the existence of a degeneration, or after an epileptic paroxysm, the muscular irritability increases and the tendon reflexes are exaggerated. This is very well illustrated by a case that came under my care some time ago. The patient was a young man who had had syphilis several years before my attendance began. When I saw him he was clearly suffering from thickening of the meninges, causing pressure on the right rolandic area, producing complete motor paralysis of the left side. The tendon reflexes on the paralyzed side were distinctly increased. Under treatment he made a perfect recovery. Here, then, we have a case where the cerebral inhibitory influence was destroyed by pressure. The cerebrum, no longer acting on the spinal centres, these became overactive, and hence the exaggeration of the tendon reflexes. The fact that there was a complete recovery from the motor paralysis, and a restoration to the normal condition of the knee-jerk, proves beyond a shadow of doubt that there had not been in this case any degeneration of the pyramidal tracts. The existence of the increased tendon reflex along with the absence of contracture and muscular rigidity, led me to form a favorable prognosis, and to exclude the presence of degeneration in the pyramidal tracts. This opinion was fully sustained by the history of the case under treatment.

In cases of cerebral hemorrhage the tendon reflexes may be enfeebled or abolished, provided the apoplexy was of sudden origin. If the blood escapes rapidly and in considerable quantity there may be a sufficient degree of shock to the nervous system to destroy all muscular tone, and produce, for a time at least, a paralysis of a perfectly flaccid type. To the absence of the deep reflexes in such cases no specific prognostic value can be assigned—the real causes of the abolition of the tendon reflexes being the position and the suddenness of the hemorrhage rather than its extensive character. In the great majority of cases of cerebral hemorrhage the reflexes soon return, and in the few instances where such is not the case, it may be that the pressure also involves the cerebellum. Should the pressure be at all marked on the cerebellum, so as to arrest its tonic influence upon the spinal centres, the tendon reflexes will not return so long as this latter state of pressure lasts. In the event of the hemorrhage being in the cerebellum primarily, even though there be no hemiplegia, there will most certainly be either diminution or abolition of the tendon reflexes, and approach toward the flaccid condition of the muscles. In cerebral hemorrhages the knee-jerk soon returns and becomes greater than the normal. In the event of cerebellar hemorrhage, the knee-jerk is absent or reduced in strength. Should the damage done by such a hemorrhage be permanent, then the knee-jerk would be permanently lost. On the other hand, if the blood-clot pressing upon the cerebellum be absorbed, the reflex may again return, and even become exaggerated, provided there be a cerebral lesion of such a character as would give rise alone to exaggeration in the tendon reflexes.

In the case of tumors in the cerebellum the knee-jerk is usually wanting. The size and position of the tumor will have much to do with this. If the pressure of the tumor be sufficient to destroy the influence of the cerebellum over the cord, so that the latter no longer receives from the former its accustomed stimulus, the patellar reflex will be absent. In my article on "The Knee-jerk," in the MEDICAL RECORD, November 28, 1891, I drew attention to the fact that this phenomenon was entirely absent in a case of cerebellar tumor under my observation, and offered what appeared to me to be the only true explanation for its absence, commenting at the same time on Gowers's views of these cases. Since the date of the above article I have had another good example of tumor in the cerebellum. There was well-marked cerebellar titubation, and, at the same time, entire absence of the knee-jerk. Osler, in his recent work, remarks, page 846, that "cerebellar incoördination has only a super-

ficial resemblance to locomotor ataxia; the knee-jerk is present, there are no lightning pains, no sensory disturbances; while, on the other hand, there are headache, optic neuritis, and vomiting." With regard to the knee jerk, such has not been my experience; and in the event of an intracranial tumor being diagnosed, the absence of the knee-jerk would lead me to locate it in the cerebellum. In the case just mentioned I knew that the knee-jerk was active and well pronounced prior to the commencement of the tumor in the cerebellum. Here, then, we have an example where the knee-jerk was present in health and disappeared with the development of the tumor.

What is the relation between the exaggeration of the knee-jerk in cerebral lesions and the descending degeneration that follows from them? This question has been much discussed and is not yet fully settled. Some hold that the knee-jerk only becomes exaggerated after several weeks, when the descending degeneration has been established. Others, again, claim that this is only a coincidence, but not a condition. This I regard as the correct view to take. First, we meet with cases of cerebral lesions in which the knee-jerk becomes exaggerated almost at once, but certainly before time has elapsed for the occurrence of descending degeneration. All that there has been time for is simply the removal of cerebral inhibition over the spinal centres, and this fact alone is amply sufficient to explain the exaggeration of the tendon reflexes. In the second place, we notice the absence of the knee phenomenon in cases of cerebellar tumor. Here we have material for close study. The cerebrum still retains its control over the spinal centres, and yet there is no reflex, provided the cerebellar disease is extensive enough to destroy its influence over the cord. In the third place, we have cases of transverse lesion of the cord, where, after a long time, no return of the knee-jerk takes place. I know of one case, now twenty-two months since the date of the injury to the cord at the level of the sixth dorsal vertebra, and though the paralyses, both motor and sensory, are of the most complete degree possible, yet there is not the first indication of the knee-jerk. Certainly degeneration in the pyramidal tracts has taken place long ago. Fourthly, cases are now recorded going to show that after cerebral injuries the tendon reflexes became greatly increased, the patient dying too soon after the injury to allow a descending degeneration to have occurred, and where none was found post-mortem. From these facts we can safely argue that the knee-jerk is not due to the existence of a degeneration in the lateral tracts, and on the other hand, because the knee-jerk is exaggerated we cannot diagnose a sclerosis nor a degeneration in these portions of the cord.

In cases of injury to the spinal cord, as fracture dislocations, the absence of the knee reflex, especially after the lapse of several weeks, is a very bad omen. In such cases it indicates that the cord is completely pulpified; and consequently the prognosis must be devoid of hope. In all the cases reported by Bastian, Bowlby, and Hughlings Jackson, where the cord was completely destroyed in its transverse diameter, the knee-jerk never returned. In my own cases the same law has been followed. In one case the cord was destroyed by an angular curvature. There was abundant degeneration, but during the illness no knee reflex. The curvature was at the fourth dorsal, and therefore well above the spinal centre for the patellar reflex; the case just mentioned above of an injury of twenty-two months' standing without any return of the knee reflex. In another case of dislocation, between the sixth and seventh cervical vertebræ, there was no return of the knee-jerk at the end of five weeks, a time long enough for degeneration. In another case of hemorrhage into the substance of the cord in the upper dorsal region there developed a severe local myelitis. The patient lived three weeks. There was no knee reflex nor ankle clonus. Post-mortem, the cord was found at the seat of the hemorrhage to be perfectly softened and devoid of all the histological characters of cord tissue. (In two other cases, which I saw with my friend, Dr. Gunn, there had been fractures of the spine, with total loss of the knee reflex. No reflex occurred in either. The injury in one case was at the tenth, in the other at the eighth dorsal vertebræ.) These cases all support the rule that, in a complete transverse lesion of the cord, the knee-jerk will be lost at once; and that the lapse of sufficient time to establish a full degree of degeneration will have no effect whatever in bringing about its reappearance or causing it to become exaggerated. In all cases of transverse myelitis, spinal cord hemorrhages, traumatisms of the cord, if we observe an abolition of the tendon reflexes, an unfavorable prognosis ought to be given. On this occasion Charcot is very positive, and my own cases would justify no other conclusion.

The knee-jerk is worthy of very close study in all cases of transverse myelitis. Bastian has called attention to the loss of this phenomenon on several occasions; and F. T. Miles has also mentioned the same fact. In four cases of transverse myelitis which I have seen, the knee reflex was absent in three, and in these there was no improvement. In these cases I gave an unfavorable opinion on account of its absence. In the fourth case the knee reflex was retained, and the patient made a considerable degree of improvement, but never a perfect recovery. There were rigidities and contractures left. So far, then, as the material at our disposal goes, I would say that in a transverse myelitis, with complete loss of the knee-jerk, the prognosis is of the worst kind possible in a rather unpromising class of cases at the best. On the other hand, if it is retained, or increased, we should be justified in holding out a greater degree of hope as to the amount of improvement likely to take place. It would appear from a careful examination of data that the degree of myelitis that is sufficient to cut off the cerebral, or inhibitory, control over the cord, while the cerebellar influx still acts on the cord, is not so great as that in which the influence of both cerebrum and cerebellum are cut off. In other words, it appears that a milder degree of myelitis may shut out the control of the cerebrum than is requisite to prevent the action of the cerebellum in producing the reflex excitability of muscles and their tonic contraction. In the milder forms of myelitis, the patellar reflex would likely remain, or even be increased, whereas in the more intense forms this sign would be lost.

In all diseases or injuries of the motor areas of the brain, causing a loss of control over the spinal cord; in all injuries and diseases of the motor paths, capsular, crustal, or pyramidal, by which the influence of the cerebral cortex is cut off from the spinal centres, there is developed a condition of extreme excitability of the reflexes. Such conditions as spastic paralysis following some lesion in the motor tracts, primary spastic paraplegia, cerebral spastic paralysis of children, the ataxic paraplegia of Gowers, and multilocular sclerosis are all conditions in which we meet with an exaggerated condition of tendon reflexes. The sooner the knee-jerk becomes increased in these cases, and the greater the degree of this increase, the worse must our prognosis be. The reasons for this gloomy prognosis, under such conditions, are the more extensive the damage in the motor tract the more complete will be the separation of the cerebrum from the spinal cord; and the subsequent incurable degenerations will be in proportion to the amount of motor fibres destroyed. In insular or multilocular sclerosis, as a rule, the increase of the knee-jerk is not so marked, owing to the fact that in this form of degeneration the axes cylinders of the nerve fibres are often spared to the last, and the connection between the cerebral cortex and spinal cells maintained. In a case, then, of multilocular sclerosis, as clearly indicated by its main symptoms, the early and extreme increase in the knee-jerk would be a very bad feature and would indicate that the axes cylinders were destroyed. Indeed, the date at which the

sclerosis begins to involve the axes, in addition to the medullary matter of the fibres, can in this way be approximately diagnosed. Thus it is that in cases of insular sclerosis the knee-jerk may be normal, increased, or abolished, according as the patches of sclerosis do, or do not, involve the paths connecting the cerebrum, or cerebellum, with the spinal cord.

In cases of sclerosis of the spinal cord, where several of its constituent portions are attacked by disease, the study of the knee-jerk requires careful study. In a recent number of the *British Medical Journal*, Jackson and Taylor report a case of great interest. It was that of a patient with ataxia, who had an attack of hemiplegia. As the damage done to the motor tracts by the second disease removed the controlling influence of the cerebrum from the spinal cord, the knee-jerk gradually returned on the hemiplegic side. The authors of the paper offer it as their opinion that the inhibitory influence of the cerebrum once removed, there was sufficient stimulus travelling through the postero-external column of the cord to produce the jerk. This opinion is no doubt correct. In the *Alienist and Neurologist* for January, 1892, I reported the case of a hemiplegic who became ataxic. The knee jerk on the non-hemiplegic side soon disappeared, but persisted much longer on the hemiplegic side. The reason is clear. On the paralyzed side the knee-jerk was greatly in excess, prior to the ataxia, and took a longer time to disappear, as the inhibitory control of the cerebrum was greatly lessened on that side. In cases of a sclerosis of the pyramidal tracts the knee reflex is in excess. Under these conditions, if the tendon reflex should gradually disappear, two conditions should be suspected: the concurrency of ataxia, or anterior polio-myelitis. In the former there would be the symptoms of the disease with the lightning pains. In the latter, there would be, along with the loss of the reflex, the coincidence of atrophy of the muscles and the reaction of degeneration and a flaccid exudation of the muscles.

General paresis—dementia paralytica or chronic meningo-encephalitis—is a disease we are all more or less familiar with. The only chance for the unfortunate victims of this disease is to be found in its early recognition. Unless this be done the treatment cannot be expected to yield much fruit. As I am dealing with the single phenomenon of the knee-jerk on the present occasion all other questions shall be left out of this article. The pathology of the disease is to be found in changes in the tunica of the arteries, development of lymph, connective-tissue, a stage of shrinking of these parts, thickening and opacity of the meninges, a wasting and atrophy of the convolutions. If we look at these changes for a moment we can see how all important an early diagnosis must be. The changes just outlined show clearly that the action of the cerebrum would be greatly impaired. This impairment in the cerebrum would show itself at an early date in the condition of the knee reflex. As soon as the influence of the cerebrum over the lower spinal centres begins to fail the jerk would begin to increase. The mental symptoms of paresis would distinguish it from ataxia. The suspicion once aroused that general paresis is a possibility, the knee phenomenon ought to be very closely watched. The earlier in the disease this becomes increased, and the more rapidly that increase takes place, the worse the prognosis. This is evident. The more rapid and progressive the destructive changes in the brain prove themselves to be the more rapidly will its control over the cord become. In eleven cases of general paresis that I have had the opportunity of studying, those cases did worst and advanced most rapidly where the knee-jerk was earliest increased. The more rapid the increase happened to be the more active was the march of the cerebral changes. One of my cases from the commencement of the attack till the death of the patient was only one year. The knee-jerk was most extremely exaggerated. In another case, lasting one year and a half, the patellar reflex was greatly increased and was one of the first conditions to make its appearance. Of the eleven cases, the jerk was increased in seven, in two there was little or no change, either as increase or decrease, while in two there was decided decrease. In these latter cases there was coincident sclerosis in the posterior columns of the spinal cord in one, and degenerating in the anterior cornua in the other. Charles F. Folsom, in writing on this disease, remarks that the knee-jerk is oftener increased than lessened. This is no doubt due to the fact that the chronic degenerative changes of the disease is oftener found in the cerebral cortex and meninges than in any other portion of the central nervous system. From the study of these cases I would conclude thus: 1. When the knee-jerk is little affected, the disease in the cerebrum is not very extensive; and the more rapidly this increases the more rapid will be the increase in the knee-jerk. 2. When the knee-jerk is reduced or lost there is coincident disease in the spinal cord, either of the postero-external columns, or of the anterior cornua. 3. If the disease be in the posterior columns there will be symptoms pointing to this, as found in tabes dorsalis. 4. When the cord disease is in the anterior cornua, along with the loss of the knee-jerk, there will be flaccidity, atrophy, and degeneration of the muscles, as was very well illustrated in one of my cases. 5. The loss of the knee-jerk, due to either of these morbid changes, would call for very unfavorable prognosis, and would exclude much hope of even a temporary arrest of the disease.

The next condition to which I shall direct attention is that of cerebral concussion. Of this condition I have had the opportunity of studying five examples. In these instances the knee-jerk was closely watched, and presented some features of unusual interest to every scientific physician. In one case, where the concussion was induced by the young man having been pounded on the head by some ruffians with a sand-bag, there was, after the shock had passed off, a very remarkable amount of increase in the patellar reflex. The superficial reflexes were also increased. There was no ankle clonus in this case. Rectus clonus could be very readily elicited. It was during the stage of cerebral irritability that the knee-jerk was most notably exaggerated. This case made a good recovery; and just as the cerebrum regained its tone, and the intelligence returned, the knee-jerk gradually became less active and finally sank to the normal. In another case of concussion, caused by a man being thrown out of his wagon, the condition of concussion did not improve, and the patient died at the end of six weeks. Over the cerebrum there was the condition of diffuse meningo encephalitis. In this case the cerebral cortex may safely be presumed to have been seriously impaired and its inhibitory power over the spinal centres must have been greatly reduced. During the progress of the case the knee-jerk became markedly increased. Toward the end ankle trepidation also appeared. This case is closely related to general progressive paresis, in which, as I have already shown, the knee-jerk is exaggerated when the disease affects the cerebral cortex only, or mainly. In another case of concussion a very interesting condition developed. The knee jerk on one side was reduced, though not abolished; but on the other side it was decidedly plus. Now the only way to account for this crossed condition of the patellar reflex, seeing that the patient got well, is to suppose that the cerebral and cerebellar influxes were differently affected on the two sides. On one side the cerebral inhibition was destroyed and the knee-jerk was increased. On the other side the cerebellar power was deficient and the knee-jerk became reduced. In the remaining two cases the concussion was slight, and the effects only lasted for a few days. In both, however, there was increase in the tendon reaction. In the one the response was very quick and the extent of the jerk three inches, in the other the response was also above the normal in sensitiveness, and the foot was

carried forward from four to five inches. I would therefore sum up as follows: 1. In cases of cerebral concussion, after the primary shock has passed off, the greater the amount of increase in the knee-jerk the greater the damage done to the cerebral cortex. 2. The gradual increase of the jerk is an unfavorable sign. 3. And finally, the restoration of the reaction to its normal should be regarded as of good omen.

When we turn to the cord itself, we are confronted with many new problems. Thanks to the labors of Charcot, Erb, Westphal, Gowers, and many others, much of the obscurity that once encircled these cases has been cleared up, and we now begin to see our way through what was once a tangled thicket with no beaten pathways. In primary and secondary degenerations in the lateral, or pyramidal tracts we are all familiar with the increase in the knee phenomenon. This is due to the fact, no doubt, that the inhibitory power of the cerebrum is no longer exerted in the normal way over the spinal centres; and the cerebellum is not counterbalanced by its larger neighbor. In all those cases where the knee-jerk is reduced or lost from cord diseases the arc of the reflex is broken in the cord at the junction of the sensory and motor portions of the arc. When the disease is located, as it is in locomotor ataxia, in the postero-external columns, the damage is done at the termination of the sensory portion. In those cases where the disease is in the anterior cornua the circuit is broken at the origin of the motor portion. The more rapidly the disease or degeneration advances in the hot zones, or in the anterior cornua, the more rapidly will the knee-jerk be lost. It is here that its great value comes, as it enables us to measure to a very considerable extent the marches that the morbid processes are making. In the case of disease in the postero-external columns there will be loss of the knee jerk, together with sensory symptoms, and the absence of flaccidity and degeneration in the muscles. When the anterior cornua are implicated there are present both flaccidity and degeneration of the muscles, with absence of special sensory symptoms. Now, it is clear that the more rapidly and completely the knee-jerk is lost in the above conditions the more rapidly is the disease making its inroads and the less favorable must the prognosis become.

In ataxia, a period of quiescence in the disease can often be dec ded by the fact that the patellar reflex is not decreasing in amount. In anterior cornuitis the stationary or returning condition of the reflex are good features, as they show that the destruction of the cells in the anterior horns is either non-progressive, or that there is some improvement. In a case or paraplegia from pressure, as in Pott's disease, there is usually an extremely exaggerated condition of the reflexes, and foot and rectus clonus may be readily detected. This excessive condition of the deep reflexes by no means justifies the opinion that there is a condition of degeneration, as I have seen several such cases recover. But here comes in the point to which I now call attention, that as recovery begins to set in, and the pathological process affecting the cord are ameliorating, the knee-jerk begins to decrease in extent and activity. Thus we have in the study of this phenomenon a key to enable us to some extent to read the changes that are going on in the cord.

In the combined forms of spinal cord degenerations the value of the knee-jerk still holds good. When the lateral tracts and the anterior cornua are both involved, the condition known as amyotrophic lateral sclerosis of Charcot, the reflex would be exaggerated so far as the disease in the pyramidal tracts is concerned, but it would be reduced or lost so far as the cornual degeneration is concerned. If this degeneration involved the centre for the knee reflex, which C. S. Sherrington has shown to be at the origin of the fourth lumbar root, the reflex would be lost. In the other combined condition, the ataxic paraplegia of Gowers, we have again one factor, degeneration in the pyramidal tracts, which increases the reflex, and another factor, degeneration in the posterior columns, which lessens the reflex. In both of the above diseases it will easily be seen that the knee-jerk deserves very close study. By its loss we can approximately determine the amount of injury done to two portions of the cord, namely, the anterior horns on the one hand, and the posterior root zones on the other.

I. Babinski, formerly chief of the clinic at the Sâlpêtrière, in the *Archives of Experimental Medicine and Pathological Anatomy*, November 2, 1891, puts on record two cases of compression of the spinal cord in which there was complete motor paraplegia. In one of the cases there was loss of sensation, in the other sensation was retained. There were recto vesical symptoms in both cases. In one case the disease was at the level of the fourth dorsal vertebra, in the other it involved the fourth, fifth, sixth, and seventh cervical roots. A very careful examination of the cord in both cases after death revealed the important fact that there was no change in the cord itself. There was neither ascending nor descending degeneration found in any of its constituent elements. The disease was without the cord. Kadner and Druschky have each reported a similar case. Now the great feature in all these cases was the entire absence of the knee jerk. There was, in other words, a complete motor paraplegia of the flaccid type.

To the above cases I shall add the notes of one I saw in consultation. The man was laying the floor in a building in the course of construction. He was in a stooping position, when a block of timber fell from some distance and struck him on the back, bruising severely the integument over the lower three cervical and the first dorsal vertebræ. He had to lie quiet for a short time; and when he attempted to walk he found that he had almost lost control over his arms and legs. There was severe pain. He was taken home, and treated by rest and the application of an ice-bag to the injured part. The pain increased, and by the following day all motion and sensation was gone. I saw him on the third day. The diagnosis made was that of pressure from hemorrhage. The knee-jerk was absent. There was considerable inflammatory action. The bladder and rectum were both affected. At the end of one month from the date of the injury the sensation had returned fairly well; but there was no return of motor power. Now the question arose, what were the chances of recovery? The knee-jerk was still absent on both sides. If the cord had been injured transversely through its entire thickness, so far as to abolish the jerk, there would have been degenerations by the end of four weeks. The injury is situated so as to implicate the roots of the bronchial plexus; and we should find degeneration in the muscles of the arms when tested by the electric currents. This was not the case. For, though the muscles were quite flaccid, the reaction of degeneration was wanting. I therefore concluded that the cord was not destroyed and that the anterior roots had a healthy connection with the anterior cornua, and that therefore the nutrition of the muscle was well maintained. Putting the two facts together, that the knee-jerk was entirely gone and that there was no muscular degeneration, I came to the conclusion that the cord was subjected to pressure, but that it was not structurally changed. The prognosis was therefore more hopeful. After a lapse of six months, the patient is able to walk, though not yet well. There are no indications of any form of chronic degeneration in the cord. From the above five cases, we conclude: 1. That when there is positive evidence of disease of injury to the spinal cord, the condition of the patellar reflex should be closely noted. 2. If the reflex is absent, and continues absent, there is one of two conditions—a complete transverse lesion, or a pressure on the cord without any actual tissue changes in it. 3. If the condition be one of total destruction of the cord in all its thickness, the muscles supplied by the nerves coming off at the seat of injury will atrophy, and there would be the reaction of degeneration. 4. If there be no reaction of degeneration, while

the knee-jerk is lost, we may conclude the cord itself is still intact, and a recovery within the range of possibility. In such cases, it is only the dynamic functions of the nervous system that are deficient or held in abeyance.

Another condition in which the knee-jerk is lost is multiple neuritis, when the nerves playing a part in its mechanism are affected. Of this condition I have published the notes of eighteen cases. The reflex arc in this condition is broken in its peripheral portions, either sensory or motor; the knee-jerk is lost, as it is in locomotor ataxia, or in anterior polio myelitis; there will be flaccidity and atrophy of the muscles as in the latter disease, and pains as in the former. The pains, however, of neuritis differ from those of ataxia in being more like rheumatism. The pains are constant; there is tenderness on pressure, tingling, and other paræsthesia. In ataxia the pains are momentary, sharp, and stabbing in character. To produce the sensory and motor disturbances, found in polyneuritis, by disease in the cord, both posterior columns and anterior cornua would have to be diseased—a combination that has not as yet been found in any case. If, then, we meet with a case of flabby paralysis, with loss of knee jerk, more or less reaction of degeneration, tingling and numbness, tenderness on pressure, absence of sharp, stabbing pains, we may conclude that the case is one of neuritis. In many of these cases the knee-jerk may be entirely absent and yet the person able to be around on foot; but there is a characteristic stiff, stoppage gait. In Landry's paralysis there is not, according to Hun, Gowers, etc., the pain, tenderness, and sensory disturbances found in neuritis. In the case of neuritis, when the anterior crural nerve is not involved, the knee-jerk would not be lost. In arsenic, lead, and alcoholic paralysis, I have noted the knee-jerk carefully; and in all the cases where there were leg pains and a pseudo-ataxic gait the jerk was lost or very much reduced.

To the late R. L. McDonnell, of Montreal, belongs the credit of calling attention to the knee-jerk in diphtheria. In this disease it is frequently absent. The question at once arises, How does the diphtheritic poison act on the nervous system so as to cause this sign to disappear? Is there always a multiple neuritis present, when the jerk is absent? To this latter interrogation I think a negative answer must be given. The toxalbumins found in the system during an attack of diphtheria are, I think, sufficient to account for the absence. These poisons may act on the nerve-tissues of the body in some manner other than by calling into existence a neuritis, so as to lessen or destroy the inherent excitability of the muscles. This feature I shall refer to when speaking of the condition of a deficient amount of oxygen in the blood. I have noted instances where the jerk was lost at the very inception of the attack, and when all sensory disturances were wanting; and in which the attack passed off, and the jerk again returned, without any neuritis. The fact, however, that the jerk is absent, shows that the poisons of the disease are acting very directly on the nerve system; and consequently very important conclusions, of much prognostic value, may be deduced. Of 100 cases of diphtheria, in patients over four years of age—as very little can be expected from the jerk at an earlier age—it was absent in 61. Among the 39 in whom the jerk was not lost, neuritis in some part occurred in 9. In the 61 where it was lost, neuritis was found in 34. Thus, of the group without the loss, less than one-fourth had neuritis; whereas in those with the loss, over one-half had neuritis, subsequently. From my cases I would conclude: 1, In doubtful cases of sore throat, the loss of the knee-jerk would point to its being an attack of diphtheria; 2, that the loss of the jerk does not prove the existence of a neuritis; and 3, that the chance of neuritis is greatly increased where there is the loss, and, *per contra*, the prognosis is not so good.

In the *British Medical Journal* for February 13, 1892, J. Hughlings Jackson contributed a short note on the knee-jerk, in conditions where the blood is supervenous. This aspect of the case deserves close attention. There are some cases of apoplexy in which the jerk is lost, and Jackson suggests that this may be due to the venous condition of the blood, as we know it is in some cases. I have not yet had an opportunity of testing this as yet. After an epileptic fit the reflex is increased in some, lost in others. When the cerebral inhibition only is lost, the jerk must be increased. On the other hand, if there be a highly venous condition of the blood, or, if the epilepsy be due to cerebellar disease, as I have shown (New York Medical Journal, September 5, 1891) may be the case, the jerk will be lost. A short time ago I was sent for one morning to see a family near me who were affected by coal gas from the stove. The mother and her two sons, aged fifteen and eleven years, were the only persons in the house. They had gone to bed, and were under the influence of the gas till morning. The milkman called at the house in the morning, and, failing to elicit any response, he forced open the back door. On seeing the condition of the things he came for me. In the cases of the mother and youngest son, the asphyxial state was pronounced, and the knee-jerk entirely absent. It gradually returned as the venous condition of the blood passed away. In the eldest son the condition of asphyxia was not great, and the jerk was decidedly exaggerated, becoming less again as the blood became properly aerated. This latter case is very instructive, as it shows that a moderate degree of venosity lessens the inhibitory power of the cerebrum, and the jerk becomes greater; but as the blood gains oxygen the power of the cerebrum is restored and the jerk comes back to the normal. In another case, that of a boy aged nine, there was impending suffocation from acute laryngitis and œdema glottidis. The lips were very livid and the surface of the body dusky. At this stage the knee-jerk was gone. The day after the intubation of the larynx the venosity had passed away, and the jerk was present. These cases are not given as anything new, but simply as a corroboration of the views set forth in J. H. Jackson's note already referred to.

In alcoholism the knee-jerk is worthy of attention. I have made in all five observations, at different times, on persons who at the time of the examinations were inebriated. In none was the degree of drunkenness extreme. The persons were all able to walk, but with a very unsteady and zigzag gait. The speech was affected in all. The jerk was increased in all. The explanation for this is most likely to be found in the action of the alcohol weakening the inhibitory power of the cerebrum. It would be interesting to know whether or not the reflex is lost in those cases of extreme alcoholism, when the breathing is stertorous and the blood badly oxidized. I have not yet met with such a case, but on my first opportunity I shall bring the matter to the test.

How about the jerk in men in perfect health? My answer is that it is very seldom absent. If the tests be made with care, the jerk can be obtained in nearly all cases. The use of a hammer instead of the hand, or, locking the person's hands together, as recommended by Jendrassik, will elicit it when the ordinary plan might fail. I have made two hundred tests in perfectly healthy men whom I was examining for life insurance. I did not find it wanting in one. In two it appeared deficient, but was increased at once by holding the hands together. Now it is here I make the distinction between health and disease. When the loss is due to disease I have never found any of the plans cause an increase. On the other hand, as just stated, when the jerk is deficient, and there is no disease, placing the hands together, and making strong voluntary effort at once causes a perceptible increase.

Sterility Following Typhoid Fever.—It is said to be a popular belief in England that a man who has had typhoid fever in his youth is incapable of begetting children. Why he should be sterile is not explained.

THE RADICAL CURE OF INGUINAL HERNIA —BASSINI'S METHOD ILLUSTRATED—WITH REMARKS ON RECURRENT AND VENTRAL HERNIA.[1]

By SAMUEL E. MILLIKEN, M.D.,

LECTURER ON SURGERY AND SPECIAL LECTURER ON HERNIA AT THE NEW YORK POLYCLINIC.

With the advent of antiseptics the surgeons were not long in trying to find some operative procedure which would relieve the thousands of beings suffering from hernia. Up to the era of cleanliness, or antiseptics, the peritoneum was entered with the greatest reluctance, and then as a last resort, being practically limited to those cases of strangulated hernia which had baffled all palliative measures. Taxis was, no doubt, often carried too far, and when the operation was necessitated, it was considered very skilful to be able to relieve the constricting band without entering the hernial sac. During that period the various subcutaneous methods were instituted, silk and silver-wire sutures being employed for closure of the hernial opening. The number of cures effected in this way can best be illustrated by saying that such operations are entirely out of date.

Heaton's Operation.—The subcutaneous injection of a solution of white-oak bark into the inguinal canal can be termed a daring, rather than a scientific, procedure. Having been able to follow a number of these cases from the time the injection was made until the hernia recurred, and subsequently had cutting operation performed, I feel that my observations are convincing.

The danger from peritonitis is of little importance, for in not a single case have I seen such symptoms arise, and it was proven on dissection that the fluid had sometimes been placed on the serous surface, along the canal, but not infrequently it was found to have been deposited in the surrounding structures instead. All that can be expected from this method is a temporary barrier to the protruding viscus, as the infiltrated mass, the result of the irritant, will eventually be absorbed, leaving only the stain of the white-oak bark.

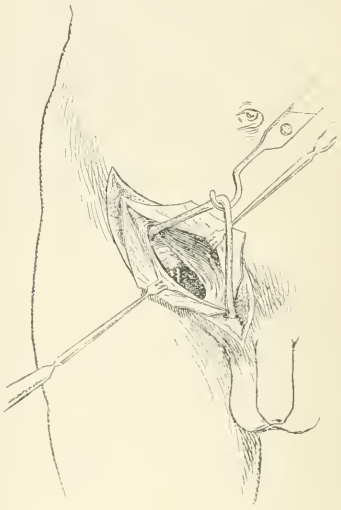
The Cutting Operations.—Before describing the method under consideration, I shall endeavor to mention a few of the points at fault in some well-known methods.

1. **Macewen's.**—Which consists in the formation of a pad by throwing the sac into folds and invaginating it into the inguinal canal.

The first and immediate danger to be anticipated is sloughing of this fibro-serous membrane, the vitality of which must necessarily be lowered. When suppuration does occur, a sinus may remain from a few weeks to several months. One case has come under my observation in which two years had elapsed without any inclination for it to close, and in this instance the hernia had recurred as well. Should immediate union of the wound be obtained, it is nature's endeavor to remove this or any other foreign body that may be so placed; hence absorption sooner or later.

2. **The Open Method.**—In which the inguinal canal has been so successfully replaced by a cicatricial plug, and which offers such flattering immediate results, has afforded me a most admirable opportunity of studying the self-destruction of adventitious tissue.

Six weeks after the operation, which is the usual time that advocates of this procedure keep their patients in bed, a contracted cicatrix, from two to three inches long and one-quarter of an inch broad, prevents very successfully even the slightest impulse. A number of these patients have come under my observation, the larger proportion of them having worn no truss until the recurrence had taken place. This precaution seems to be a very wise one under such circumstances, as even the most delicate pressure from without added to the constant force being exerted from within, would no doubt hasten a process that is inevitable, *i.e.*, stretching and thinning of the cicatricial mass. The recurrent herniæ observed after this method, during the first six months, have been rather a separation of the cicatrix, usually at the site of the internal ring, from the musculo-tendinous structures adjacent. It is, however, the more gradual process, the thinning of the cicatrix, which concerns the comfort and ultimate welfare of the individual operated upon. I have observed repeatedly, and demonstrated the same in my lectures at the New York Polyclinic, peristalsis of the



intestine through the cicatrix. It is needless to say that the wearing of the most perfectly fitting truss occasions great discomfort.

One other complication that sometimes occurs in these cases, as in other abdominal sections where cicatricial union is obtained, is the adhesion of the peritoneum, which causes the patient such agonizing pain on coughing.

3. **Suture of the External Abdominal Ring.**—The best demonstration, to me, of the inefficiency of the closure of the external abdominal ring, is brought out in a paper by Dr. Bull, read before the New York State Medical Association, September, 1889, in which he was able to report forty cases; all were inspected, at periods varying from a few months to six years.

"Twenty of this number had been operated upon by excision and ligation of the sac; the remaining twenty had excision and ligation of the sac, together with suture of the pillars of the external abdominal ring."

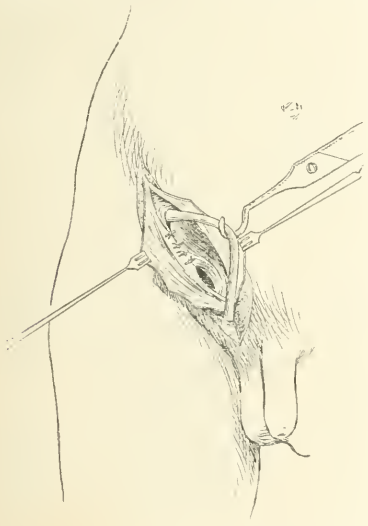
According to the report, "By both methods, in all varieties, there were sixty per cent. of cures and forty per cent. of failures."

With the above clinical facts, I am convinced that the external abdominal ring has nothing to do with the causation of hernia. Whether it be closed with catgut or silver wire, after ligation and excision of the sac, the percentage of recurrence will continue to be large just so long as the abdominal contents are allowed to enter the inguinal canal. For once there, the closed pillars will soon yield under this constant strain. The condition of the sac, I must confess, is quite secondary to that of the internal ring, as is demonstrated by the frequency with which reducible hydrocele is met with, demonstrating that there exists a communication with the abdominal cavity without a hernial protrusion. It is to the operation for reconstructing the inguinal canal that I wish to call the attention of the Association, believing that the method will appeal to one and all as thoroughly scientific and practicable.

[1] Read before the Texas State Medical Association, April 27, 1892.

Cleansing.—The pubis and scrotum being cleanly shaven, the skin should be soaped and scrubbed with a coarse brush; next the whole area must be washed with plain water; subsequently ether is applied to remove all oily material, and lastly with a 1 to 1,000 corrosive sublimate solution. Great care should be used in thoroughly cleansing the glans penis, which is so very liable to infect the wound during the operation.

Operation.—*Bassini's Method.*—The patient being thoroughly anæsthetized (I prefer ether, administered with the "Ormsby Inhaler"), an incision is made, beginning at the spine of the pubis, and extending upward and outward. The upper extremity should be about two inches internal to the anterior superior spine of the ilium—everything is divided down to the tendon of the external oblique. The latter is incised over a grooved director, passed into the external abdominal ring, superficial to the hernial sac and cord structures. To expose the internal ring properly, the tendon should be cut for about two to two and one-half inches. The upper flap is now freed from the underlying structures and reflected toward the median line until the conjoined tendon, composed of the internal oblique and transversalis muscles, is brought well into view. The lower flap or segment of the anterior wall of the inguinal canal is next dissected from its underlying fascia, until the shelving process of Poupart's ligament is exposed. These flaps being held back by retractors, the next point of technique is to hook up with the index-finger the cord



structures as they pass over the spine of the pubis, and lift them and the hernia out of their bed. This blunt dissection should be continued until you have reached the internal ring. The hernial sac, without reducing its contents, should now be isolated; this is best done by dividing the overlying structures on a grooved director until you have exposed the bluish-grey thickened membrane for a small area. This coat is raised with a small pair of rat-toothed forceps, that the hernial contents may not be injured when the opening is made. The entrance into the peritoneal pouch should be manifested by the escape of a small amount of serum, unless it be an incarcerated or strangulated hernia, when the fluid may be tinged with blood. The contents having been examined, all adhesions that may exist are tied off with fine catgut. Large masses of omentum should be ligatured, not necessarily at the most distal point, but where the greatest constriction exists, and it is advisable to use the transfixion method. Occasionally it occurs that the obstacle to reduction is a fibrous constriction situated within the internal ring. That is, however, easily detected at this stage of the operation, and can be divided without danger by incising upward. Returning to the treatment of the sac, it must be completely separated from the cord and other adherent tissues well within the internal ring, and a moderate amount of traction made uniformly at all points, which is best accomplished by a series of artery forceps held by an assistant.

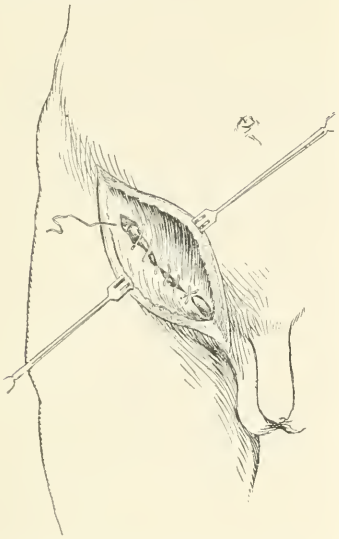
Ligation with catgut is done also by the transfixion method. The sac is excised, leaving the pedicle about a quarter of an inch in length, which immediately retracts into the abdominal cavity. When a congenital hernia exists, the sac should be cut off one inch above the testis. The reforming of the tunica vaginalis is of no importance, and the prevention of hydrocele will thus be attained. This completes the first step of the operation.

Second Step.—The upper and lower flaps, composed of the segments of the tendons of the external oblique, being well retracted, the cord structure held out of the operative field by a blunt hook or the finger of an assistant, the conjoined tendon on the upper side is now united to the shelving edge of Poupart's ligament, by a series of interrupted chromatized catgut or kangaroo tendon sutures. The Macewen blunt-pointed needle accomplishes this admirably. The needle, when passed through Poupart's ligament, must not include more than one-quarter of an inch from the edge. The relaxed posterior wall of the canal, composed of the transversalis fascia, may be included in the upper grasp of the needle, along with the conjoined tendon. From four to six sutures, inserted in this way, will be sufficient to firmly unite the musculo-tendinous structures, forming a new posterior wall for the canal. In this reconstruction care must be taken not to constrict the tissues of the cord.

Third Step.—The formation of the anterior wall of the canal is accomplished by suturing the recently divided external oblique tendon, continuously, with fine catgut, throughout its entire length. This re-establishes the valve-like condition of the inguinal canal. The skin wound is closed with interrupted catgut sutures after the insertion of a small glass drainage-tube, from two to two and one-half inches long, into the lower angle of the wound, and the following dressing is applied:

Iodoform powder (or what is preferable, fine crystals) should be spread along the line of suture and around the drainage-tube; on this a strip of Lister protective or rubber tissue, two inches wide and long enough to overlap one inch at the ends, a perforation being made for the drainage-tube; moist iodoform gauze, six layers thick and sufficiently long and broad to overlap the wound two inches on all sides, also perforated for the drainage-tube; next a larger compress of moist sublimated gauze is placed over the upper part of the wound and held in position by a two-inch strip of surgeons' rubber adhesive plaster, extending almost entirely around the pelvis. An intervening layer of rubber tissue should be used to prevent infection from the plaster. Over the drainage-tube is placed sublimated gauze, very loosely distributed; next, cotton, and lastly it should be covered by rubber tissue, one foot square, which is perforated for the penis and held in position by a Hank truss or simple spica bandage. The advantages of having the above dressing are several: First, infection from without is prevented by the rubber tissue, which is most external, and by the small strip which is in immediate contact with the skin. By means of the adhesive plaster alone can perfect retention of the deeper dressing be accomplished. However, the most important point in this detailed dressing is the arrangement of the drainage-tube, which can be removed at the end of thirty-six or forty-eight hours by simply taking off the external dressing and not disturbing that which is in immediate contact with the wound. After its (the drain) removal the point of exit should be iodoformized well, covered with loose sublimated gauze, and a new protective

dressing applied. Where animal sutures have been employed the wound should heal under one dressing, even in cases of strangulation.



Confinement in bed for three weeks has been the maximum. Since I have been performing this operation this has occurred in but two cases, in each of which I endeavored to discard the glass tube and adopt capillary drainage with strands of catgut. In each of these cases a moderate amount of retention took place and primary union was prevented. No case should be permitted to leave bed before a fortnight, as too great a strain will be put on the freshly united structures.

After-treatment.—In all my cases, when this or any other radical operation has been performed, I insist on the wearing of a truss for six months. The choice of apparatus is a subject worthy of consideration, as it would not only be uncomfortable but hazardous to apply a truss with a powerful spring; on the other hand, a light and uncertain support must be avoided. Any of the frame or complete band trusses, preferably with a water pad, will give the greatest comfort to the patient, and will afford the most uniform and perfect support to the inguinal region.

Conclusions.—No attempt has, or shall be made to present to the Association a statistical paper, as sufficient time has not elapsed in any of my cases to pronounce them radically cured. Suffice it to say, that during the past eighteen months I have operated after this plan on ten cases, and as yet not a single recurrence has appeared. However, with the author's permission, I shall make a few quotations from Professor Bassini's book, which was published in 1889, and as late as September, 1891, he wrote me that the percentage of cures was quite as large, in proportion to the number operated upon, as at the time of the original report.

Statistical Remarks.—"Two hundred and sixty-two were operated upon, ten of these were strangulated. Of the two hundred and fifty one non-strangulated cases, one hundred and eight were observed from four and one-half years to one year; thirty three from one year to six months; ninety-eight from six months to one month; seven recurred; four, the results are unknown; one died of shock."

To Mr. Bert Wilder, of *Harper's Weekly*, I am indebted for the truthful and artistic illustrations.

ON THE STERILIZATION OF MILK AT LOW TEMPERATURE,

With Description of a New and Simple Apparatus Applying the Principle of Pasteurization.*

By ROWLAND GODFREY FREEMAN, M.D.,

Assistant Physician to Roosevelt Hospital, Out-patient Department; Pathologist to St. Mary's Hospital, New York.

Since attention has been directed to the large number of bacteria in the ordinary milk supply, some at least of which appear to be deleterious, efforts have been made to more or less completely kill them by means of heat sterilization. This has, until recently, been accomplished by exposing milk to a temperature of 100° C. (212 F.) for a period varying from twenty minutes to an hour and a quarter. After an experience of six years with milk so prepared, the general verdict of the profession is, I believe, that while sterilized milk is most valuable in the treatment of gastro-intestinal disorders, it is very often unsatisfactory when used as a regular food, seeming for some reason not to fulfil the condition of perfect nutrition. Analyses explain this, in a measure, by showing that various chemical changes take place in milk between 75° C. (167° F.) and 100° C. (212° F.) and that these changes become more marked as the temperature becomes higher. According to Leeds,[1] sterilization at the boiling-point of water or 100° C. (212° F.) causes the following modifications in the milk: The starch liquefying ferment is destroyed and coagulated. A portion of the lactalbumin is coagulated. Casein is rendered less coagulable by rennet and is acted on slowly and imperfectly by pepsine and pancreatin. Proteid matters attach themselves to fat-globules and probably bring about a less perfect assimilation of fat. Milk-sugar, by prolonged heating, is completely destroyed. According to Koplik,[2] "from the temperature of 75° Celsius upward there is a separation of the serum albumin of the milk; the caseine loses its coagulability to rennet, and at 85° C. amounts of rennet, which for the raw condition of milk are found sufficient to act, cease to be effective." Heuppe, quoted by Koplik,[2] considered that, from a physiological standpoint, milk is best sterilized, if possible, under a temperature of 75° C. In the meantime it has been shown by investigators that temperatures lower than 100° C. (212° F.), if continued for a short time will destroy a very large proportion of the germs, and will destroy with certainty many pathogenic germs which find their way into milk either from the cow or as external contaminations.

The problem then presents itself to devise a method of preparing milk which shall destroy by efficient means the contained germs, and yet in the least possible degree interfere with its nutritive qualities. In other words, the minimum temperature used must be high enough to destroy most of the germs; the maximum must be so low as will not alter materially the chemical composition of the milk. Pasteur [3] found in 1868 that exposure of wine for a short time to 55° C. would prevent its spoiling; other observers have found that 60° C. (140° F.) to 70° C. (158° F.) was sufficient to kill bacteria. The term pasteurization is now used for any process by which the germs of wine or milk or other fluid are destroyed by the use of heat between 55° C. and 80° C. followed by rapid cooling. It should be mentioned that pasteurization does not usually render all germ-containing fluids absolutely sterile, all spores are not deprived of life and certain vegetative forms may prove invulnerable. But a sufficient number of such forms may be killed as to check, if not permanently hinder, fermentative changes. The rapid cooling is necessary to prevent the spores which remain in the fluid from developing.

Of the thoroughly known pathogenic germs which may exist in milk, the bacillus tuberculosis, in the light of our present knowledge, is one of the most important. As the result of very elaborate and recent experiments by

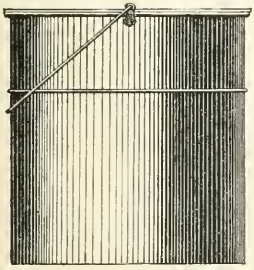
* Read before the Section of General Medicine of the Academy of Medicine, New York, June 20, 1892.

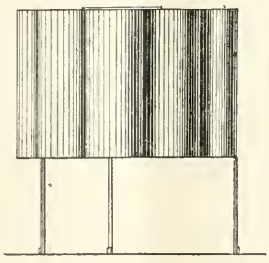
Yersin,[4] Granchier and Lidoux-Libard,[5] and Bitter,[6] one may conclude that any of the following exposures to heat will destroy the bacillus tuberculosis in milk: 75° C. (167° F.) for ten minutes; 70° C. (158° F.) for fifteen minutes; 68° C. (154½° F.) for thirty minutes.

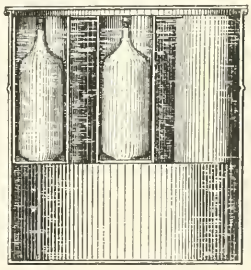
It is practically difficult by microscopic examination, by inoculation experiments, or physical examination of cattle, to determine that the milk of any cow is free from tubercle bacilli. It seems important, therefore, that pasteurization should be carried out with a sufficient temperature to destroy with certainty the bacillus tuberculosis. Concerning other pathogenic bacteria, Van Geuns[7] found that a few seconds' exposure to 60° C. (140° F.) would kill the cholera sporilla, the Finkler Prior bacillus, the typhoid bacillus, and the pneumococcus of Friedlander.

While it is important to destroy the pathogenic germs above described, the beneficial effects of sterilized milk, especially in summer diarrhœa, are undoubtedly due to the destruction of other, as yet little known forms which the milk, especially in summer, is apt to harbor. Experiments already done in low temperature sterilization of milk and those to be detailed below, would lead us to the belief that these unknown deleterious germs may also be destroyed by this temperature.

From what has been stated one may conclude that a temperature of not less than 70° C. (158° F.) will render milk sufficiently germ-free for infant food, and that a temperature of less than 80° C. (176° F.) will not injure milk materially. Methods of pasteurizing milk in quantities have been presented to the public both in Germany and in this country, but as far as I know no such method for household use has been published. Such an apparatus should be a simple affair for use on a stove. The problem of sterilization at 100° C. (212° F.) was fairly simple, since the boiling-point of water is a definite temperature, and boiling produces phenomena easily recognized by anyone. To devise an apparatus for a lower temperature seemed more difficult, because the use of a thermometer is to be avoided. It occurred to me that by immersing a certain definite amount of milk in a







properly proportioned bulk of boiling water, the source of the heat having been removed, the temperature of the milk could be raised to about the desired point, *i.e.*, 75° C. (167° F.). Of course the bulk of the boiling water required depends both on the bulk and the temperature of the milk to be heated. The amount of water in my apparatus is such that in raising the temperature of the milk through 60° C. (108° F.) it loses itself an equivalent of heat, so that when the milk reaches its maximum temperature the water surrounding it is of the same temperature. The apparatus which I present is constructed on this principle of the distribution of heat through two fluids of unequal temperature, and will raise the contained milk through about 60° C. of temperature (from 15° to 75° C.) and keep it at about its maximum temperature for half an hour, after which there is a loss of about one degree every fifteen minutes.

The apparatus consists of two parts, a pail for the water and a receptacle for the bottles of milk. The pail is a simple tin pail with a cover; there is a groove extending around the pail to indicate the level to which it is to be filled with water, and supports inside for the receptacle for the bottles of milk to rest on. The receptacle for the bottles of milk consists of a series of hollow zinc cylinders fastened together; this fits into the pail so that the top of the cylinders are almost level with the top of the pail. I have experimented with other forms of receptacle, including an ordinary tin pail, but find this form the best. Either of two such receptacles may be furnished with the pail, one which will take ten six ounce bottles, or one for seven eight-ounce bottles.

The apparatus is used in the following way. The pail is filled to the level of the groove with water, covered, and put on the stove to boil, the receptacle for the bottles being left out. Now the bottles of milk are filled and stoppered with cotton, and dropped into their places in the cylinders. Sufficient water is now poured into each cylinder to surround the body of the bottle. This is very necessary for conduction of heat. When the water in the pail boils thoroughly it is taken from the stove and set on a mat or table or other non-conductor, the lid is removed and the receptacle containing the bottles of milk is set inside. The lid is now put on again and the whole is allowed to stand half an hour, after which the bottles of milk are put in a refrigerator. In case there is no refrigerator in the house, measurably the same purpose may be attained by replacing the hot water in the pail by cold water, or, better, ice and water. The water must be renewed at frequent intervals until the bottles of milk are of the same temperature as the water used. Water from the faucet at this season, June, is just 20° C. (68° F.), which is the temperature to which it is desirable to cool the milk as rapidly as possible. When cooled, ice may be put in the water in the pail, the bottles being left in place, or the bottles may be taken out and put in a cool place.

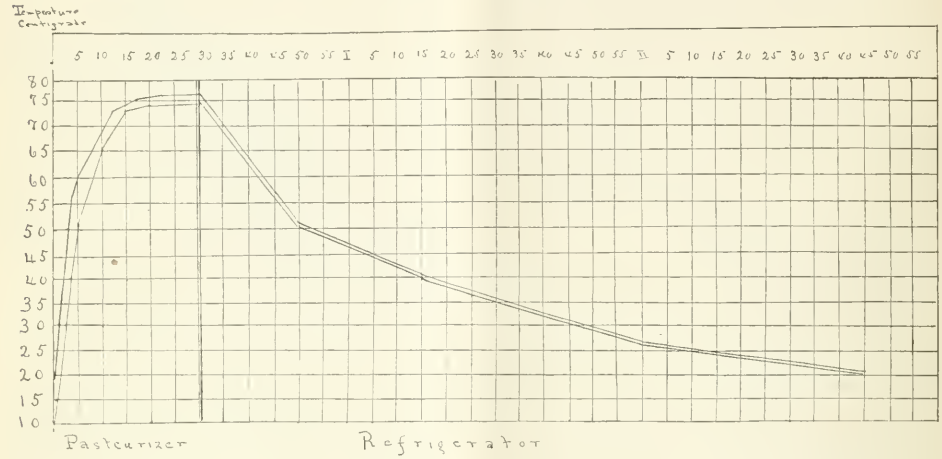
Milk subjected to this process and put immediately into a refrigerator and kept there shows usually no change for several days. A precipitation of caseine takes place in a week or ten days.

I have made careful observations of the temperature of the milk in this apparatus during the various stages of the process, by means of thermometers in the bottles which pass out through holes in the covers. The temperatures I have recorded are the temperatures at the bottom of the bottles, since this part of the milk heats more slowly than the top. The middle bottle does not have exactly the same temperature as the side bottles, but the variation does not exceed two degrees. The accompanying chart shows best the rapidity of the rise of temperature and the constancy of the temperature during the last fifteen or twenty minutes of the half hour exposure. It also shows well that milk at a low temperature is elevated through a greater number of degrees than milk at a higher temperature. This is an important fact and tends to eliminate any error from the uncertainty of the temperature of the milk when put in the apparatus. I have found that the temperature of milk in a refrigerator during warm weather varies from 10° C. to 19° C. (50° F.

to 64° F.), but is usually between 13° C. and 16° C. (55° F. to 61° F.). Such milk would reach about 75° C. (167° F.) in this apparatus. Referring to the chart, we see that the temperature rises through 40° to 45° C. (72° to 79° F.) in the first five minutes, and that a temperature of 70° C. (158° F.) is reached in eight to ten minutes, depending on the temperature of the milk introduced. In leaving the milk in this apparatus half an hour we expose it to a temperature of over 70° C. and 80° C. (158° F. to 176° F.) destroys tubercle bacilli, and, according to Van Geuns, destroys also the typhoid bacillus, the cholera bacillus, and the pneumococcus of Friedlander, also most of the ordinary milk-germs, and does not injure milk.

3. Milk may be pasteurized by simply immersing it in a proper proportion of boiling water, the source of heat having been removed, and leaving it so immersed for half an hour.

Table Showing the Rise of Temperature of Milk at the Bottom of the Bottles in the Pasteurizing Apparatus, followed by the Rate of Fall of Temperature in a Refrigerator. Two Separate Experiments.



(158° F.) for twenty minutes. The cooling in the refrigerator is slow. It requires two hours and fifteen minutes to reach 20° C.

I have made a series of experiments at the Bacteriological Laboratory of the College of Physicians and Surgeons to test the efficiency of this apparatus in the pasteurization of milk. Specimens of milk obtained at different times and from different sources have been examined to determine the number of bacteria contained in one cubic centimetre before and after pasteurization. This was accomplished by planting in gelatine plates. The result of this work is given in the accompanying table from which it may be seen that while the raw milk used contained from 8,000 to 230,000 and more bacteria to each cubic centimetre, the same milk after pasteurization usually contained none.

Table Showing the Number of Bacteria in 1 c.c. of Milk Before and After Pasteurization for One-half Hour.

Summary.—1. Both clinical and chemical evidence lead us to believe that milk is injured for infant food by the formerly practised methods of sterilization by boiling or steaming, or even by any temperature above 80° C. (176° F.).

2. Pasteurization with a temperature between 70° C.

4. In the apparatus here described the proper proportion between the boiling water and the milk has been calculated and tested, and by the use of the apparatus in practice ordinary milk in summer is found to have been rendered practically sterile, and keeps unchanged in a refrigerator for several days.

Tobacco-Smoke.—A large number of investigations have been made by Dr. Tassinari on the influence of tobacco-smoke on the germs of cholera, anthrax, and pneumonia. His method of research was to line the interior of hollow balls with gelatine containing the germs of the diseases named; tobacco-smoke was then passed through these globes for from ten to thirty minutes. The surprising fact was then established that at the expiration of that time the bacilli of true Asiatic cholera and of pneumonia were completely destroyed, whatever the kind of tobacco employed for the purpose. The gelatine was absolutely sterilized by the tobacco-smoke. The anthrax bacillus was more resistant, however, while the bacillus of typhoid was scarcely acted on at all.

Death of the "Human Ostrich."—A dime-museum freak, known as the "human ostrich," died a short time ago in St. Louis. According to the press despatch the post-mortem examination "showed that the stomach, its walls and lining were entirely normal, but literally filled with the nails, screws, tacks, and broken glass which the man had swallowed. A remarkable feature of their presence there was the fact that none of them was encysted, and that there was not one instance of perforation of any part of the stomach or throat."

COUGH: SOME OF ITS CAUSES AND ITS TREATMENT.[1]

By CHARLES D. ROY, A.B., M.D.,

ASSISTANT TO THE CHAIR OF DISEASES OF EYE, NOSE, THROAT, ETC., SOUTHERN MEDICAL COLLEGE, ATLANTA, GA.

The euphonic word which forms the caption of this paper is one familiar to every physician and to every household. No gilded mansion nor humble hut has ever been able to bar its doors against its entrance. No clime, no class, no age can claim it as its own, for its name is but the heritage of the whole world. The aged mother whose tottering frame leans upon the arm of a stalwart son has been a victim of its wrath; the little swaddling infant, the first jewel which crowns a mother's maternity, has not escaped the sufferings which it brings. As the family sits around the hearthside at eve, how often does a croupy bark from one of the little ones strike terror in a mother's breast, heralding, as it were, the approaching sleepless night. It is not surprising, then, that I should bring before you to-day a subject so commonplace, and yet one of such extensive domain, for it is always the every-day subjects which seem unlimited in their scope. Nor do I wish to place myself before you as one with narrowed views, for that day is fast being relegated to the past which considers that the knowledge of a physician or surgeon must be limited entirely to his own line of work. They are the best physicians who are able to be specialists in any branch of medicine. The tendency to "hobbies" is now too prevalent among all classes of the medical profession, and often to the detriment of their patients. Some would have us believe that most of the subjective ills of mankind are due to refractive errors or muscular insufficiencies of the eyes, while our brother gynæcologist would take issue with such and prove beyond the shadow of a doubt that the same troubles are caused from a prolapsed ovary or an undue size of the same. The subject I have chosen is one limited to no class of physicians, but especially from the general practitioner does it often draw the most thoughtful consideration. It is not my purpose to bring forward any startling innovation, nor to treat in their entirety the diseases with which cough is associated—a task far too momentous—but simply to group the etiological factors of this symptom in such a manner as to aid us in making a ready and reliable diagnosis.

A cough, according to Landois, consists in a sudden violent expiratory explosion, after a previous deep inspiration and closure of the glottis, whereby the glottis is forced open and any substance, fluid, gaseous or solid, in contact with the respiratory mucous membrane is violently ejected through the open mouth. This act, as we all know, is voluntary or involuntary: voluntary in so far that we can produce the act at pleasure, and involuntary or reflex in that a point is often reached in bronchial irritation or from any other cause whereby, with all our will power, we are unable to stay the act. Kohts, in Landois' Physiology, has located a coughing centre a little above that of the inspiratory in the medulla oblongata. According to this experimenter, the afferent paths are the sensory branches of the vagus, and the efferent lie in the nerves of expiration and those that close the glottis. That there are other paths, there can be no doubt, as can often be seen from clinical experience; though by far the largest amount of work is done by the latter nerves. So important is the par vagum in our coughing miseries, that the refreshing of our minds with the anatomy of its sensory branches will not be amiss.

Dr. Leaming, of New York, has well said, "the par vagum is a chummy, friendly nerve. It is the source of all our friendships. We dine together, meet together, drink together by its influence." The pneumogastric or tenth cranial nerve has its origin from a nucleus in the medulla oblongata along with the ninth and eleventh nerves, and, passing forward, it leaves the cranium through the jugular foramen, being enlarged at the latter point into what is known as the jugular ganglion. Its main sensory branches, and hence those most involved in cough and most important to us, are as follows:

1. The auricular branch, coming off from the jugular ganglion, receiving connecting branches from the glossopharyngeal or ninth, crossing the facial and giving sensory branches to the posterior portion of the auditory meatus and the adjoining part of the outer ear.

2. The pharyngeal plexus is aided in its formation by branches from the par vagum and from the ninth. From this plexus sensory branches supply the soft palate, arch and probably the posterior portions of the inferior turbinate bones.

3. The superior laryngeal, the sesnory nerve to the base of the tongue and all the mucous membrane of the larynx, is pre-eminently the nerve of cough.

4. The pulmonary branches of the vagus join the anterior and posterior pulmonary plexuses, and hence, from this source, supply sensory (cough-exciting) fibres to the whole bronchial system, lungs and pleura.

5. The senscry fibres to the stomach and also to the liver, and through connections with the great solar plexus, probably send fibres to the organs of generation.

From this brief anatomical exposition, we see from what sources irritations may come in producing cough, and being thus fortified in our knowledge, we are better enabled to seek the proper source. The character of a cough depends largely upon the locality and nature of the cause of which it is a symptom. For we must bear in mind that we are not discussing a disease—a distinct entity—but a symptom of a disease or morbid state, and it is the latter condition which determines its character. Various words have been used as descriptive of peculiar kinds of cough, and it is well for us to pause for a moment and consider in our minds the meaning of such adjectives most frequently used, as brassy or metallic, hoarse, spasmodic, jerky, hacking, croupy, raspirg, etc.

When we speak of cause in relation to cough, we of course mean those pathological conditions with which it is associated, by the removal of which the cough ceases. We cannot say that enlarged faucial tonsils always produce a cough, but that they are sometimes a causal factor, we must admit, since a persistent cough often ceases upon the removal of these organs. Hence, in this article, we shall try to consider all those factors which, in the light of clinical experience, have been found to have aided in the production of this symptom. In all diseases of the lungs and pleura cough is a prominent symptom, but to discuss the diseases of these organs would extend this paper beyond a reasonable length; so that, with the exception of a passing remark, the points of the article will be confined to the respiratory tract above the bifurcation of the trachea. To make a classification of causes with distinct lines of demarcation is difficult indeed, but simply to aid us in the study, I have made the following arrangement:

a, **Causes.**—1. Such as are dependent upon an acute pathological state of the respiratory tract. *a*, Lungs and pleura; *b*, larynx and trachea; *c*, pharynx.

a, *Lungs and Pleura.*—In all acute and chronic diseases of the lungs and pleura, cough is a prominent symptom, as one would naturally expect from the anatomical distribution of the pulmonary plexus. How familiar to many of you is the short, dry, jerky cough with the accompanying stitch in dry pleurisy? How, also, the deep basilar cough of pneumonia? With a pulmonary cough there is usually the accompanying expectoration, sometimes labored and even requiring several efforts before it succeeds, while in pleurisy there is nothing to eject, and, consequently, the cough is dry and hacking. In acute and even chronic bronchitis, cough is one of the most distressing symptoms, and one which causes the patient many a sleepless hour. The accumulation of secretions in the bronchial tract is often the most irritating factor,

[1] Read before the Annual Meeting of the Georgia State Medical Association.

for we note how aggravated a cough is in the early morning hours before the expulsion of the secretions which have accumulated during our sleeping moments. Who has not seen this, the most distressing symptom, in phthisis pulmonalis? Cavities in the lungs are always exciting factors, for it is here that the dirty, purulent secretions find a never-ceasing abode. Dr. Leaming, of New York, has recently called attention to the first paper of Dr. G. P. Camman, in which the latter dwelt upon the management of lung cavities by position, thus showing how one of the most harassing symptoms of this dreaded disease could be alleviated. The idea is based upon the fact that if you make the patient lie so that the cavity can be thoroughly emptied by cough and gravity, and he then be made to turn back, allowing an interval for its refilling, he can in this way secure at night several hours of needed rest. If the cavity is not thoroughly emptied, the constant running over, as it were, from the mouth of the reservoir acts as a continual source of irritation.

b, Acute Inflammation of the Larynx and Trachea has, as one of its commonest symptoms, cough, either dry or moist. The congestion thus occasioned by the inflammatory state, together with the increased amount of secretion which is usually present with it, acts as an irritant to the nerve terminals in this locality. Upon this theory, therefore, the richer a portion of the tract is in nervous supply, the more irritable will it be, and the more harassing and persistent will be the cough. Physiologists tell us that a cough cannot start from an irritation in every portion of the respiratory tract, but that there are certain areas only which are supplied with nervous irritability. These are the glottis respiratoria and the bifurcation of the trachea; other portions, they say, as, for example, the true vocal bands, are more or less insensitive. These facts are based exclusively upon the experiments of Kohts and Vulpian. Theoretically, this may all be true; but, practically, we know that cough comes from irritation in any portion of the tract, and in inflammatory conditions we cannot limit this state to any circumscribed area. The character of a cough originating in the larynx and trachea is determined by the character of the existing pathological state or the anatomical formation of the region, according to the age of the individual The tone of all coughs is modified by the condition of the larynx, and especially that of the true vocal bands, whether there be true œdema or exudative material upon their surface. If, with a croupy cough, there is free expectoration, how much more favorable is the prognosis than when the exudation is membranous and clings with deathlike tenacity to the surrounding parts!

The treatment of this symptom is but the treatment of the disease, the main factor being in lessening the hyperæmic condition of the mucous membrane. All remedies for cough originating from this region are given to act locally, whether administered internally, to be eliminated, through the respiratory tract, or applied directly by means of inhalation—a method much the surer. I will not stop to mention all the remedies which have been brought forward as specifics for cough due to this pathological state, but will allude only to those which have proven of most value in my hands. I dislike always to administer any form of opium if it can possibly be avoided, and for this reason I use an inhalation treatment almost entirely. Dr. Bishop, of Chicago, a few months ago, advocated the use of a spray of menthol camphor for various laryngeal troubles, and since that time I have used the remedy with marked success in laryngeal and tracheal coughs

While Dr. Bishop first called attention to the mixture of camphor-menthol, Dr. Hobbs, of Atlanta, was the first to bring prominently before the profession the use of both menthol and camphor in the treatment of nasal diseases.

Triturate together equal parts of camphor and menthol, forming a deliquescent mass, and of the mixture make a 1 to 4 per cent. solution in albolene, and with a suitable oil spray producer allow the patient to inhale it three or four times daily. Another remedy I have used with success is a mixture of terebene in oil vaseline (one drachm to two ounces), inhaled in the same way as the first. In a cough accompanying a severe laryngitis, the compound tincture of benzoin, given by hot steam inhalation, as recommended by Lennox Browne of London, is a most valuable remedy.

c, Pharynx.—In acute follicular pharyngitis, cough of a hemming character is sometimes present, due to the unusually irritative character of the follicles as the current of air strikes its surface. The treatment consists in the thorough destruction of the follicles, best done with the galvano-cautery point, followed with astringent applications of nitrate of silver.

2. Functional, or such as are dependent upon pathological states or deranged functions, more or less chronic: *a*, nasal; *b*, pharyngeal; *c*, laryngeal; *d*, auricular; *e*, gastric; *f*, hepatic; *g*, reproductive.

a, Nasal.—All physicians who have ever worked to any extent in the nasal cavities know how frequently cough is excited when the mucous membrane covering the turbinates is touched with a probe. I have a little patient upon whom a violent fit of coughing is produced whenever a spray is used in the anterior nasal fossæ. This, of course, is reflex irritation but for a moment, and ceases when the probe or spray is removed, but what we see here as a momentary cause becomes a continuous one in enlarged turbinates or septum spurs. Dr. Beverley Robinson, of New York, speaks of coughs of this character as due to posterior hypertrophies of the inferior turbinate, producing pressure and irritation by contact with the septum. Some rhinologists have found areas in the nose more sensitive than others. Dr. John McKenzie, of Baltimore, found the posterior portions of the inferior turbinates the most irritable area, while Mr. Lennox Browne, quoting Hack, found it in the anterior portion. Nasal neuroses, dependent upon abnormalities in the nasal cavities, have of late taken a prominent place as causal factors in producing many symptoms before unknown. That such abnormalities play an important rôle no one can deny who has seen such benefits accrue to patients relieved of these morbid conditions. Deviated septums, spurs, enlarged or hypertrophied turbinates, polypi, etc., can all, by reflex irritation, be a cause of cough, hence it behooves a physician to examine thoroughly into the nasal cavities when no discoverable lesion can be found elsewhere as a causal factor in the production of this symptom. To go into the methods of treatment of the different forms of nasal diseases that cause cough would make a lengthy article of itself; suffice it to say that every source of possible irritation should be found and removed. Hypertrophies are best removed with the galvano-cautery, and polypi should be thoroughly extirpated with the wire ecraseur. All septum deviations and spurs, when prominent enough to be a source of irritation, should be removed by whatever method the operator chooses.

b, Naso pharynx Adenoids, besides an obstacle to free nasal breathing, are sometimes an active source of coughs, as is also an enlarged third or pharyngeal tonsil. The pharyngeal tonsil is a collection of lymphoid tissue, usually in the median line of the vault of the pharynx, and while often overlooked, it is frequently the source of a post-nasal catarrh and a causal factor in the production of the symptom in question. If such a patient be examined with a post rhinal mirror, this globular, red, protruding mass will be seen in the vault, and, in the majority of cases, coated with a ropy, mucous secretion. The only permanent cure for this condition is the complete extirpation of the offending masses, best done with some post-nasal forceps. Adenoids should always be removed as soon as possible, that the attendant train of symptoms may be eradicated.

c, Pharynx.—An elongated uvula is another source of cough, and must not be overlooked, its character being of a hacking nature without expectoration. I dislike to men-

tion the uvula as a causal factor, from the fact of its abuse and the rough treatment it has received at the hands of many physicians. How often has a poor, innocent little uvula of, perhaps, a little increased length, been clipped when no other cause for a cough could be found, and the patient thus be made to suffer for the ignorance of the operator! I have seen several cases where too much of the uvula was excised and thereafter the patient made to suffer the inconvenience of an incomplete closure of the post nasal space in deglutition. One must observe whether the uvula is relaxed or falls with ease upon the base of the tongue before looking upon it as a source of irritation. Cough due to this cause is most troublesome at night when the patient is lying down and the organ falls against the pharynx. The treatment consists in the reduction of the size of the organ, either by medicaments or ablation of a portion. Astringents should always first be tried, and, these failing, provided the length warrants it, abscission can be performed, usually with success. One unaccustomed to the performance of the operation will invariably excise too much and leave the patient in a more uncomfortable state than the one previous. A large portion of the uvula being muscular, it has a tendency to contract, so that its muscular portion should not be cut. In the majority of elongated uvulæ, one will always see between the mucous membrane and the muscle a distinct line of demarcation, and it is here that the line of clipping should be made. Long forceps and scissors are all that is required. Do not cut off too much, is my injunction, if you do not want the unsavory benediction of your patients.

Hypertrophied Faucial Tonsils.—While not frequent, the above condition is sometimes the cause of a persistent cough, especially in children. Dr. Beverley Robinson, of New York, makes mention of the fact, and Lennox Browne, in speaking of a neurotic cough, believes that there is always an objective cause. He says the commonest of these is the irritation of enlarged tonsils, and cites two cases where the removal of these organs was followed by the cessation of that symptom. He further says, "recent experience leads me, even where the tonsils are not enlarged, to suspect adenoid growths in all cases of reflex spasmodic cough. Adenoids and enlarged tonsils so commonly exist together, that a thorough inspection for both is always demanded." Beverley Robinson says, "hypertrophy of this structure (tonsils and adenoids) gives rise to congestion of the lower naso-pharynx, and this increases the sensory excitability." The treatment of this condition is the removal of the enlarged tonsils by whatever method the operator chooses. McKenzie's tonsillitome is a favorite instrument with many and has proven very satisfactory in my hands. The means resorted to matters not, just so they are removed.

Enlarged Lingual Tonsil.—The name tonsil, in this connection, is misleading, for the morbid condition rather signifies a collection of lymphoid tissue, lobulated in appearance, at the base of the tongue, especially at the sides. This lymphoid glandular tissue is sometimes the cause of a harassing, rasping cough, especially in singers or public speakers, among whom this condition is most prone to exist. So common is it among this class that I immediately look for it when singers consult me for treatment. Numerous mention has been made of this condition in the recent literature upon the subject. A. Ruault in the *Archives de Laryngology*, as late as June, 1888, speaks of it, as does also Dr. J. W. Gleitsman, in the New York MEDICAL RECORD for December, 1887. Associated with the cough is a feeling of constriction in the throat and the sensation as if a foreign body were present whenever the act of deglutition is performed. The treatment consists in its removal. If lobulated and large, it can be removed with the wire ecraseur; otherwise, the occasional application of the galvano-cautery will be found more serviceable.

d, Laryngeal.—Under this head must be mentioned the growths, whether external or internal, benign or malignant, which, by their presence, irritate some filaments of the superior laryngeal nerve, and cause cough. Removal of such growths will prove the only satisfactory treatment. The accumulation of a dirty, purulent secretion in the larynx, attendant upon an existing atrophic rhinitis, is frequently a source of irritation and productive of a cough, which is only removed by the cure of the nasal disease.

e, Aural.—Cough, from irritation of the auricular branch of the pneumogastric, is an occasional, though infrequent, occurrence. Many cases have been reported where the removal of impacted cerumen, foreign bodies, etc., from the external auditory canal has relieved a cough of long standing. Such a case I saw a few weeks ago in that of a medical student, who had exhausted all the known remedies for his cough, only to experience relief when a large mass of impacted cerumen was removed. In the last edition of Dr. Roosa's work on "The Ear," he devotes a special paragraph to the consideration of this subject, under the heading of "Ear Cough," and quotes numerous authorities who hold the same view. The treatment consists in the thorough removal of all abnormal substances in the external auditory canal, especially if they be pressing upon the membrana tympani.

f, Gastric Hepatic Reproductive.—Gastric neuroses manifested by reflex irritations in other portions of the body are no uncommon occurrences, especially in the work of the general practitioner. The anatomical relationship to the great solar plexus of nerves makes the stomach a centre from which many nerve impulses originate, and which may thus prove a centre for many reflex phenomena. The three great vital centres, the brain, heart, lungs, are greatly influenced by its morbid condition or any functional derangement of the same. A "stomach-cough" is no infrequent occurrence with children. Flatulency, distention, loss of tonicity, are some of the frequent concomitant symptoms. Young children from under the watch care of their mother frequently overload their stomachs with cakes, candies, fruits, etc., the result of which, manifesting itself at bedtime by an incessant cough, is quickly relieved by an efficient emetic or a good dose of oil. Indigestion plays no small part as a causative factor in this symptom, and hence a well-regulated digestive apparatus is a matter of necessity as well as comfort.

g, Hepatic.—Organic rather than functional derangements of the liver are more apt to act as excitants of a cough. Alcoholic subjects especially are more prone to suffer with this symptom, whether they be suffering with a hypertrophic or atrophic cirrhosis of this organ. A case recently under my charge affords a typical example of the condition in question.

A German, male, aged forty-five, was referred to me by his family physician on account of an incessant cough of the most explosive nature, which had yielded to no course of treatment. The patient gave a good family history, and to all appearances his present physical condition, save the cough, was excellent. By the habit, acquired in his fatherland, he was an excessive beer-drinker with an occasional interspersion of more spirituous liquors. His pharynx was very sensitive to the least manipulation, and vomiting would be produced with the slightest provocation. By degrees a thorough examination was reached. The nasal cavities showed nothing as a causal factor, and the pharynx, save the anæmic, soggy condition of the mucous membrane throughout the oral cavity, which one usually finds in chronic alcoholics, presented nothing abnormal. The retching would cause the epiglottis to appear unusually large, but when quiet was restored to the parts, no pathological changes could be seen within the larynx. I then turned my attention to the stomach and liver, and found him suffering with a condition of chronic gastritis, and, by palpation and percussion, the liver was found to be much enlarged and hardened, with slight tenderness. Whenever firm pressure was made over the hepatic region, a paroxysm of coughing was immediately started. The morbid process

had so far progressed that no remedies succeeded in staying the pathological process. I doubt not but that many of you have often seen a nervous, hacking cough, dependent upon an engorgement and torpidity of the liver, quickly relieved by some hepatic stimulant or mild cathartic. In malarious districts this condition is frequently an exciting factor, and a thorough regimen of treatment must be instituted before the symptoms will abate.

Before closing, I must mention a cough which is sometimes present about the age of puberty, seemingly dependent upon the condition of the reproductive organs or that of the blood. In *The Lancet* of December, 1890, Sir Andrew Clarke had an article entitled, "Remarks on the Barking Cough of Puberty," and cites several cases of this condition occurring in his practice, both in boys and girls. Dr. Leaming, of New York, who has since called attention to this subject, has reported such a condition occurring in a young girl, suffering from chlorosis, following an attack of mountain fever. The late Sir Morell Mackenzie has also reported such a case. That there is a close relationship between certain conditions of the reproductive organs and certain nervous phenomena in other portions of the body, no one, I am sure, will deny, for day by day the correlation of our bodily functions is growing in importance Dr. John McKenzie, of Baltimore, has called attention to certain nasal conditions coexisting with a peculiar state of the reproductive organs, which, from their constancy, do not seem to be entirely fortuitous. In all such cases the treatment must be general, the aim of the physician being to restore the body to as normal a condition as possible by rectifying all morbid states in individual organs.

In speaking of the various causes of cough, I have made no mention of that disease of childhood known as whooping-cough, since my aim has been to consider only those pathological conditions demonstrable on ocular inspection, as irritating factors in the production of this symptom. Whooping-cough is a germ disease, as is the almost universal consensus of opinion, and, like all others of its class, the specifics for its cure are legion.

My task is over, but if I shall incite you to a closer discrimination of the various causes of this every-day symptom, and not to treat all coughs indiscriminately by certain "stock prescriptions," my aim will have been fully satisfied and your patients likewise blessed.

Clinical Department.

DEATH FROM PULMONARY EMBOLISM FOLLOWING OPERATION FOR APPENDICITIS.[1]

By FRANCIS J. SHEPHERD, M.D., C.M.,

SURGEON TO MONTREAL GENERAL HOSPITAL, ETC.

In view of the fact that appendicitis and its complications are yet exciting much attention in both medical and surgical circles, in the Old World and the New, anything tending to increase our knowledge of the subject will, I feel, be acceptable. This is my excuse for reporting a case of appendicitis which, though not successful, is interesting from a pathological point of view.

The number of fatal results following operations for this disease is no doubt much greater than the reported cases would lead us to believe, and death results in many cases, not as an effect of the operation, but because of its too tardy performance, septic peritonitis having already set in. I am convinced that some cases are septic from the first, and that no operation, however early it may be performed, will be successful. Such cases are those where no pus is found, but the appendix, and perhaps the cæcum, are in a gangrenous condition.

The most frequent cause of death after operation for appendicitis is, no doubt, septic peritonitis, but I am not aware that any deaths from pulmonary embolism have been placed on record.

In those cases where the patient has suffered from frequent attacks of appendicitis, and as a result there is a considerable amount of inflammatory tissue about the appendix and cæcum, thrombosis of the iliac veins would very easily take place. Any disturbance at the time of the operation, or afterward, might set free a portion of the thrombus, and this, after passing through the heart, might easily block up the pulmonary artery. Such I imagine was the train of events in the case I am about to relate, and in which the cause of death was verified by post-mortem examination.

James W——, aged thirty-five, bookkeeper, had his first attack of appendicitis in November, 1890. At this time he had rigors, high fever, and vomiting, and his physician discovered a tumor in the right iliac fossa. He was confined to bed for some three weeeks. In the winter of 1891 he had two slight attacks, which caused him to remain in bed a week. In August, 1891, he was again seized with pain, vomiting, and high fever, and again a tumor appeared in the right groin, which was exceedingly tender on pressure. His physician, Dr. Blackader, asked me to see him, and as his condition was serious and the symptoms not abating, I advised immediate operation. He was admitted into a private ward in the General Hospital on August 22d, and operation was at once performed. Before operation his temperature was 103° F.

Operation.—The usual incision was made and the peritoneal cavity opened. To the inner side of the incision a mass was seen which on breaking through its wall discharged a quantity of fetid pus. The cæcum was easily found, and also the stump of the appendix, which had sloughed off and had disappeared. The abscess cavity was carefully cleansed and stuffed with iodoform gauze, which was not removed for three days. The patient went on well for seven days, with a normal pulse and temperature, and was progressing toward recovery most satisfactorily. On the evening of the seventh day he suddenly complained of severe dyspnœa and intense pain, and died in less than an hour.

An autopsy was held next day, when the following conditions were found: "Thrombosis of the external iliac vein, extending into the common iliac, lungs bloodless, and pulmonary arteries blocked with emboli. The thrombus in the iliac veins appeared to be of some standing, and was not of septic origin.

There was no trace of peritonitis, and the abscess cavity, which contained one drachm of sweet pus, was well separated by a line of adhesions from the general peritoneal cavity.

There was nothing to account for the separation of the emboli, as the patient had been making no exertion, and when the accident happened was talking quietly to the nurse.

Note.—In the discussion which followed the reading of this paper Dr. McConnell reported a death from a similar cause after operation for appendicitis; here, however, the separation of the embolus was caused by massaging the upper part of the thigh, because patient complained of a feeling of stiffness and discomfort. Dr. Armstrong also reported a death from pulmonary embolism following operation for appendicitis. In neither of these cases was an autopsy held.

[1] Read before the Medico-Chirurgical Society of Montreal, April 15, 1892.

A Boomerang.—A quack in a Western city advertised that he had treated some thirty cases of diphtheria during the previous month, and had cured every one of them. He was thereupon arrested, and is to be prosecuted by the Board of Health for having failed to report the cases.

A Sure Thing.—Primus: "Young Dr. Neale tells me that in his specialty he has never made a mistake in diagnosis." Secundus: "What's his specialty—autopsies?"—*Judge.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, July 2, 1892.

THE OLD-TIME FAITH-CURES.

SINCE the year 1844, when A. Gauthier reported his "Recherches historiques sur l'Exercice de la Médecine dans les Temples," a number of studies have been made of sacerdotal medicine among the ancient Greeks. One of the latest of these is by M. Diehl ("Excursions Archéologiques en Grèe, 1891"). These works throw an interesting light upon the practice of medicine in olden times, but they particularly show its close resemblance to the faith-cures of to-day. The temples of Æsculapius began to take a prominent part in the social and medical life of the Greeks at about the time of the Trojan War, and they lasted as institutions until 400 A.D. The faith-cures of old, therefore, officially endured for about one thousand years. The temples of Æsculapius were usually small and modest structures. Like the doctor of to-day, they did not secure great gifts of gold; their reputation was among the poor. They were placed in some salubrious spot and had attached a corps of priests and attendants. The sick came and were placed on couches in the interior, where, after visitation from the priest, they made their vows and went to sleep. It was expected that the god would visit them in their dreams and either heal them or reveal a way for so doing. If a cure resulted the patient deposited some gift, and caused a tablet to be erected describing his disease and its cure, and rendering appropriate thanks to the deity. These gifts and inscriptions remained to ornament the temple and inspire hope and confidence in the hearts of new-comers. Some gave propitiatory offerings, *i.e.*, paid before they were cured. But this seems to have been rather unusual. The ancient Greek was of a frugal mind and only paid for what he got. Archæologists have collected many of the curious votive tablets from these old faith-cure establishments. A Lacedemonian lady had the dropsy. Her mother consulted the god at the temple of Epidaurus and dreamed that she saw him descend, cut off the head of her daughter, then hold up the trunk until all the water ran out. She woke up, went home, and found her daughter well. Another tablet describes the dream of a patient who suffered from cancer of the stomach. The god removed the cancer by a neat and painless laparotomy, and the patient awoke and was cured! If it could only be done that way now! Naturally the priests became somewhat skilful in the practical and real part of medicine. They saw that their patients received healing drugs and followed hygienic ways of living. It was from some of these practical physicians that Hippocrates learned what little he knew of medical art, expunging from it priestly mysticism and quackery.

As time passed and the ancient religion became more of a conscious deception and means of gain the temples of Æsculapius degenerated. They were sometimes started as a business venture by dishonest men, who worked them "for all they were worth," just as is done nowadays. Again, specialism entered the field. The oracle at Delphos, in order to enlarge its revenues, entered the field; the priests of Diana at Ephesus made a specialty of the eyes, and those of the temples of Venus looked after certain kinds of tumors. In order to help along the business later, a great deal of trickery was introduced; finally, human credulity could be taxed no farther, and the temples were abandoned.

In the early days, when conducted by honest priests, the temples of Æsculapius no doubt did much service. They were the sanitaria and consulting centres of the people. Their decline and fall was inevitable as Christianity grew, but it was hastened by the gross abuses of the system.

OPERATIONS FOR CANCER OF THE STOMACH.

IN a critical review of the subject of the surgical treatment of gastric cancer, Dr. A. Guinard (*Archives Générales de Médecine*) goes over the works of the past ten years and reaches some conclusions which are, we believe, wise, and ought to be thoroughly familiar to medical men. There is, he says, no cure for cancer of the stomach by operation. From this we infer that he does not find any case in which relapse has not eventually taken place. This is surely discouraging; still he goes on to say that very much can sometimes be done by the surgeon. One ought, he says, to abandon to medical treatment alone all gastric cancers which are not accompanied by pain, pyloric stenosis, and progressive inanition. One should undertake removal of a cancer only if it is small, movable, and single. These conditions only present themselves at the onset of the disease, hence every possible means should be adopted to recognize the tumor in its earliest stage. An exploratory laparotomy, which is almost harmless, should be undertaken if necessary. If an operation is determined upon, it should, as a rule, be a gastro-enterostomy. This should be the regular operation, a gastrectomy or pylorectomy is the exception. The mortality from these operations oscillates between fifty and eighty per hundred, depending a good deal upon the experience and skill of the surgeon.

Bearing upon this same subject is a recent paper by Dr. Senn, of Chicago, who discusses the question of gastrostomy for œsophageal stricture and cancer of the cardiac orifice. Here somewhat different problems are presented, for in these cases the operation alone is not usually difficult, and a temporary relief is surely obtained. Dr. Senn says: "Gastrostomy for malignant obstruction on the proximal side of the stomach, if performed at a time when the patient is sufficiently strong to survive the immediate effects of the operation, is a comparatively safe procedure, and adds from a few weeks to six or eight

months to the patient's life." "Leakage from the fistula can be prevented most effectually by making the opening in the stomach small, by the use of an inflatable double rubber bulb, through which the feeding-tube reaches the stomach, or by making an oblique tunnel in the anterior wall of the stomach, as devised and practised with success by Witzel." "Mastication of food, as a preliminary step to its introduction into the stomach, satisfies, at least in part, the sense of hunger, which is not always accomplished even by liberal exclusive gastric feeding through the fistula."

The mortality from the operation is about twenty-five per cent.

THE TREATMENT OF HYSTERIA.

In the days of Sydenham, hysteria, or "the vapors," was the most frequent of all chronic diseases, according to that eminent observer. At the present day it is perhaps less common relatively among women, but is more common, or at least oftener observed, among men. The conception of the nature of hysteria has undergone much change since the olden times, when it was thought to be a disorder primarily of the womb. For many years it was taught that hysteria was a reflex trouble; then that it was a convulsive neurosis of a general or constitutional nature. These ideas have of late been much modified, and it is now quite generally agreed that hysteria is a disease of the mind, or a psychosis. The psychology of the condition has been well studied by Janet, Möbius, and others. They note as characteristic phenomena a limitation of the field of consciousness and a disorder of the association processes, as the result of which impressions received are not properly modified and adjusted to previously acquired knowledge. Hence, they become dominant and intense, and disturb the ordinary mental equilibrium.

The conception of hysteria as a psychosis has an important therapeutical bearing. It cuts away the ground from those who would treat the disease as originating in the uterus, the stomach, the blood, or the eyes. In a critical review of the subject of the therapeutics, by Dr. Paul Blocq, of La Salpêtrière, not a word is said of uterine or ocular measures, except to condemn castration. Dr. Blocq divides the treatment into the psychical, external, internal, and treatment of special conditions. The psychical treatment is naturally the most important. It consists essentially in isolation. This measure we are told is approved and taught by Charcot. Curiously enough, no credit is given to Weir Mitchell, and other American physicians, who originated and developed it long before Charcot and his pupils took it up. The other form of psychical treatment is hypnotism, to which Blocq wisely gives a cautious approval. It has value only in certain cases.

The external measures advised are hydrotherapy, electricity, and massage. The hydrotherapy is given daily in the form of a jet, or by the wet sheet and sponge bath. Franklinism is thought to be the most efficacious form of electricity, administered in the form of the bath. In some special types, however, faradism does better. Massage is applied in all its various methods of *effleurage*, *pétrissage*, *tapottement*, etc. In general *pétrissage* is useful in the convulsive forms, *effleurage* in those with contractures.

Little reliance is placed on medication for the psychosis itself. Naturally anæmia, dyspepsia, etc., may call for proper remedies. The bromides are of little value in hysteria, according to the French school, and Charcot even utilizes the drug in diagnosticating hysteria from epilepsy. American physicians do not find it so useless, partly, perhaps, because American hysteria is not of so purely a mental type. Bromide of camphor, valerian, and zinc are advised by Blocq in cases in which there is excessive nervousness and agitation. For the attacks ether and bromide of ethyl may be used.

Dr. Blocq describes a latent form of hysteria, a hysteria minor, hysteria major, and mono-symptomatic forms. The latent hysteria is simply the psychopathic condition of children born of hysterical and neurotic parents. Such children have night terrors, are somnambulic, irritable, choleric, and lack power of attention and control. Professor Pitres advises that they be brought up away from their parents, in the discipline of schools. The advice is certainly excellent. Hysteria minor, or *petite hystérie*, is the common form of the disease, and is characterized by slight convulsive attacks and emotional crises, with various interparoxysmal symptoms. Such patients present few, if any, stigmata of the disease. Hysteria major, as its name indicates, is the most serious form. Its victims suffer from hystero-epileptic seizures, contractures, palsies, anæsthesias, etc., and their treatment usually calls for the combined application of many of the remedies mentioned.

Dr. Blocq disturbs one very common belief among physicians, viz.: that marriage is a good remedial measure for hysteria. It is, he says, quite generally agreed that marriage does more harm than good to hysterical women, and it is not to be advised unless there be special reasons for it. Surgical intervention in the shape of ovariotomy is also strenuously condemned.

The End of a Malpractice Suit.—Dr. A. F. Reed, of Holyoke, was sued by a former patient named Bissonette, who sought damages on the ground that his fractured leg had been improperly set by the defendant. The case was tried about two weeks ago and the jury brought in a verdict for the doctor. The patient, as is usually the case when damages are claimed, had repeatedly disobeyed the surgeon's injunctions, getting up too soon, taking off the splints, etc., and withal there was shortening of less than two inches. The medical testimony was wholly favorable to the defendant, proving that he had managed the case intelligently and skilfully, and that whatever want of success there was arose entirely from the patient's negligence and disobedience to the attendant's orders. We congratulate Dr. Reed on the vindication he has received, while sympathizing with him in the trouble and expense to which he has been put in defending himself from a groundless accusation.

American Medical Editors' Association.—At the annual meeting of the American Medical Editors' Association, at Detroit, Mich., Dr. J. C. Culbertson, of Chicago, was elected President, and Dr. T. D. Crothers, of Hartford, Conn., Secretary.

News of the Week.

Cheap Sterilized Milk for Tenement-house Babies.—An experiment is about to be made, during the coming hot season, in providing sterilized milk for the poor in the vicinity of the Good Samaritan Dispensary. Some charitably-minded ladies and others began in 1891 the operation of a sterilizing plant as a means of teaching the tenement house population on the East Side that something could be done for the protection of infants against some of the germ diseases incident to the hot weather. This plant has been allotted a room at the Dispensary, and milk devoid of germs will be sold below the cost of production, so as to enable it to compete with unsterilized milk.—*New York Medical Journal.*

The Mississippi Valley Medical Association will hold its eighteenth annual session at Cincinnati, October 12, 13, and 14, 1892.

American International Medico-Legal Congress.—At the first session of this Congress, held in New York in June, 1889, a permanent organization was effected and it was resolved to hold the second session on the occasion of the Columbian Exposition. It is therefore proposed to hold the session in 1893, in June, July, or August of that year, and, if the necessary arrangements can be made, in the city of Chicago. Due notice of the four days selected and the place will be given hereafter. A committee will formulate and announce the order of the proceedings, the subjects to be discussed, the arrangement and classification of the papers to be read, and the discussions thereon, which will be sent to all members and published in the journals. The enrolling fee, which will entitle the member to the "Bulletin" of the Congress, will be $3. All those who desire to enroll themselves or to read papers at the meeting may communicate with the president or secretary in New York City. The officers of the Congress are Mr. Clark Bell, *President;* Mr. Moritz Ellinger, *Secretary;* and Drs. Frank H. Ingram and W. J. Lewis, *Assistant Secretaries.*

Chicago Pathological Society.—At the recent annual meeting of this Society the election of officers was held, resulting in the choice of Dr. C. D. Wescott for President, and Dr. Elmore S. Pettyjohn for Secretary. The past year has been the most prosperous one in the history of the Society. Its membership has increased twenty-five per cent. and the attendance at the meetings has been uniformly good.

St. John's Guild.—Active preparations are being made by St. John's Guild for this season's work for the relief of the sick poor children and their mothers in the tenement-house districts during the summer months, and the Guild's Floating and Seaside Hospitals will be in full operation at an early date. These institutions are absolutely free, without the least discrimination as to color, creed, or nationality, and are supported entirely by voluntary contributions. Those desiring to aid in this useful charity may send their contributions to Mr. W. L. Strong, Treasurer, 501 Fifth Avenue, New York City.

Buffalo Ophthalmic Hospital.—A new hospital for the treatment of diseases of the eyes has recently been opened in Buffalo. The greatest pains are to be taken to exclude from its benefits any but the really poor, and if it succeeds in this praiseworthy object it will be an institution worthy of imitation throughout the length and breadth of this fair land.

International Dermatological Congress in Vienna.—The second meeting of the International Dermatological Congress will be held in Vienna from September 5 to 10, 1892. Many of the most distinguished representatives of dermatology and syphilography from all countries have promised to present papers, and the indications are that the meeting will be a great success from a scientific standpoint. The Committee on Organization, through the President, Professor Kaposi, has extended a cordial invitation to the members of the American Dermatological Association, and of the New York Dermatological Society and others interested in dermatology in this country to be present. The membership fee ($5) should be sent, with titles of papers intended for presentation, to the Secretary for North America, Dr. Prince A. Morrow, 66 West Fortieth Street, New York, or to the Secretary-General of the Congress, Dr. Gustav Riehl, Wien 1-20, Bellaria Strasse 12.

Treatment of the Tzar's Consumptive Son.—The Grand Duke George, the Tzar's second son, who, ever since his enforced return, through illness, from his Indian tour, has been under medical treatment for pulmonary disease, has been passing the winter at Abbas-Tuman in the Caucasus. A private letter from that place states that his Imperial Highness is undergoing a most remarkable course of treatment. The walls in his apartments are bare and unpapered, the furniture is of plain wood or cane, without upholstering or stuff-covering of any kind, and his bed consists only of the thinnest of mattresses. Throughout the winter only a very moderate fire has been kept up, while the windows of the Grand Duke's rooms have been continuously open. His attendants have suffered dreadfully from the cold; but his medical advisers hold that this low temperature is very beneficial to their imperial patient, as it tends to destroy the bacillus and prevent the formation of tubercle. They maintain that the progress of the disease has been arrested, and express hopes that, if the treatment which they prescribe is persevered with, the Grand Duke will in two years' time have completely recovered.

What to Do at Saratoga.—Rise at 7 A.M.; go to the spring (Congress, Carlsbad, Hathorn, or Empire), drink a glass of water, hot; walk for ten minutes; another glass of water, hot or cold; walk for half an hour to an hour. Breakfast, consisting of milk, eggs, meat, coffee, or tea diluted; avoid raw fruit, hot rolls, or fresh bread. Then go to stool. At 11 A.M., one or two glasses of Vichy (medium), walk for half an hour or so. Dinner at two; eat no fried meats or fish, no salads, no corn, no pastry, no raw fruit. Take a rest or a nap till five, then a walk or a drive. At six, one glass of Vichy. Supper at 7.30; light diet—milk, toast, eggs, stewed fruit. At nine, another glass of Vichy, and retire at ten. This plan is to be kept up for not less than three weeks, avoiding all mental excitement. If there is a rheumatic tendency, the Red Spring or magnetic baths three or four times a week Vichy with meals and Geyser at night have given me sat

isfactory results. Diabetics and patients with uric-acid diathesis do extremely well on Vichy or Kissingen in large quantities. In chlorotic and anæmic patients I have been much pleased with the effects of Columbian or Washington (the iron waters), being careful to tell my patients only to drink these waters from one and a half to two hours after eating, for, unless these directions are given, the patients always complain of severe headache after taking the water. These waters just mentioned I have found most satisfactory; but there is no doubt of the efficacy of many of the others, and the paper would be too long were I to attempt to describe the uses of each of the twenty-eight springs.—Dr. L. Rau, *New York Medical Journal.*

Warts and Porpoises.—Dr. Louis Lewis writes to *The Times and Register:* "Last month a gentleman called on me to be examined for life insurance. I noticed that the backs of his hands and fingers presented a large array of unsightly warts ('verrucæ vulgaris'), which he said had hitherto resisted all treatment, either returning or refusing to go. He went to the West Indies, and, during the voyage, shot a porpoise, which was hauled on deck, and, in cutting up the carcass, his hands were freely besmeared with the blood. To his surprise, every wart vanished in short order, and none have come back. Returning to Philadelphia to day, he presented himself to me with a perfectly clean pair of hands. I have often heard that pig's blood will remove warts, and have received the news with a large grain of salt; but here is a singular coincidence, to say the least of it, if only in the resemblance between a porpoise and a pig. I should like to give this 'remedy' a trial; but few druggists keep porpoises in stock, and I do not think I could shoot one."

International Medical Magazine is the title of a new monthly issued in Philadelphia, by the J. B. Lippincott Co., and edited by Dr. Judson Daland.

It is Reported that Dr. Robert Koch has interrupted his bacteriological studies by marrying a popular danseuse.

Corn-meal as an article of diet has been introduced into Germany largely through the instrumentality of Colonel Murphy, and "Murphy-brod," as it is called, is now sold in nearly all the bakeries.

Death of Dr. William Aitken.—Sir William Aitken, Professor of Pathology in the Army Medical School at Netley, died on June 27th. He was a member of the Royal Imperial Society of Physicians of Vienna, the Society of Medicine and Natural History, of Dresden, and the Imperial Society of Medicine, of Constantinople. He was made a knight on the occasion of the Queen's Jubilee in 1887. Sir William was the author of a standard medical text-book, in which he expounded for the first time the use of the thermometer as a means of determining the temperature of the body in cases of fever. He volunteered for service in the hospitals of Turkey during the Russian war and, afterward at different times, held several positions in the English army medical service.

Not Chloroform but Chloral.—Dr. George C. Mosher, of Kansas City, Mo., writes: "In your very thorough abstract of the proceedings of the recent meeting of the American Medical Association, in the issue of June 18th, p. 696, I am made to say in a paper on 'Delayed Labor,' read before the Section on Obstetrics: 'Chloroform by the rectum might prove useful,' when what I really said was: 'Chloral hydrate by enema was regarded as of greatest value in these cases.' Later on: 'Chloroform in the second stage of labor given to obstetric anæsthesia was frequently indicated.'"

The New York Physicians' Mutual Aid Association is now able to pay $1,000 upon the death of a member, which is the full amount allowed under the by laws. At present the number of members upon the roll is 1,106.

Regeneration of Bone.—Dr. Ricketts, of Cincinnati, is engaged upon a translation of Ollier's work on "The Experimental and Clinical Study of the Regeneration of Bone and of the Artificial Growth of Bony Tissue."

Dr. Weir Mitchell has made a discovery, not in the line of physiology but of poetry. He has found a gentleman who writes poetry with thought in it, and our distinguished colleague justly celebrates the event.

Dr. John Ridlon, who recently removed to Chicago from this city, has been appointed Lecturer on Orthopedic Surgery at the Chicago Medical College.

Reviews and Notices of Books.

Treatise on Gynæcology, Medical and Surgical. By S. Pozzi, M.D., Professor Agrégé à la Faculté de Médicine; Chirurgien de l'Hôpital Lourcine-Pascal, Paris; Honorary Fellow of the American Gynecological Society. Translated from the French edition under the supervision of and with additions by Brooks H. Wells, M.D., Lecturer on Gynecology at the New York Polyclinic; Fellow of the New York Obstetrical Society, and the New York Academy of Medicine. Vol. II. With 174 Wood Engravings and 9 full-page Plates in Color. Pp. xvi., 583. New York: William Wood & Co. 1892.

The favorable impression created by the first volume of this work is strengthened by the second, which follows it with commendable promptness. The importance of diseases of the adnexa is fully recognized, more than one-half of the volume being devoted to this subject. The almost uniform association of disease of the tube and ovary is indicated by the titles of Chapters II. and III., "Oöphoro salpingitis without Cystic Tumor," and "Cystic Oöphoro-salpingitis." The expression "ovaritis," by the way, is not preferable to "oöphoritis." Some of the compound words in these chapters are rather ponderous, *e.g.*, "sclero cystic degeneration," "micro-cystic degeneration," "obstetrico-surgical exploration," etc. Under the chapter on "Perimetro salpingitis" the author includes the conditions described as pelvic peritonitis and cellulitis. He believes that the infection in phlegmon of the broad ligament may be secondary to inflammation of the tubes, or to a peri lymphangitis, a view which indicates his conservative attitude.

Four chapters (V. to IX.) are devoted to ovarian tumors, two of these dealing with their surgical treatment. Chapter X., on "Genital and Peritoneal Tuberculosis," contains a scholarly discussion of this subject, which has assumed so much importance of late years. In considering the etiology of hæmatocele, emphasis is properly placed upon the fact that "the great majority of cases start from some tubal lesions" (ruptured ectopic gestation?). The chapter on "Extra uterine Pregnancy" presents a good *résumé* of the subject from a surgical stand-

point. Chapter XV., entitled "Cicatricial Fistulæ of the Vagina," is devoted to the operative treatment of vaginal fistulæ, preference being given to Bozeman's and Simon's methods. Emmet's work certainly deserved some recognition here. We marvel at the author's silence. This chapter is particularly rich in illustrations. The chapter on "Laceration of the Perineum" is properly supplemented by a description of Emmet's method of posterior colporrhaphy, written by the editor. The flap-splitting method is thoroughly described, as well as Martin's and Hegar's operations. The illustrations are particularly good, and we note with pleasure Mundé's excellent colored plates. The two concluding chapters, on "Disorders of the Urinary Tract" and "Diseases of the Rectum and Pelvis," translated from Auvard's recent work, supply a deficiency which was apparent in the French edition of Pozzi. The carefully prepared general index is a decided improvement on the original.

We have already indicated the chief points of excellence in Dr. Wells's edition, and need not repeat what we said in the review of the first volume. Suffice it to say that, as an index of the present status of gynecological surgery, the work is almost without a rival. While the unprejudiced American reader is willing to admit that for a foreigner Pozzi shows an unusually wide acquaintance with the work of our progressive surgeons, he can also understand that it is only natural that the author should not assign the same importance to certain distinctively American operations (notably trachelorrhaphy) as our own writers. The editor has, however, supplied many of these omissions as well as he could do without showing too great a desire to intrude his own personal views. Such criticisms and additions as he has seen fit to make have been made in an admirably discreet and modest way, which deserves our commendation. He has substantiated the claims of his countrymen wherever this has been necessary, yet without being led into the fault of bragging, which has been so often criticised by foreigners, and has detracted from the value of some of our best work in gynecology.

A Primer of Materia Medica for Practitioners of Homœopathy. By Dr. Timothy Field Allen. 12mo, pp. 408. Philadelphia: Boericke & Tafel. 1892.

"This Primer," as its preface indicates, "aims to present the characteristic features of the most important drugs used by homœopathic physicians." It may serve to refresh the mind of a physician when away from his complete symptomatology, it will help him discriminate when studying an unfamiliar pathogenesis. In its preparation comparisons "only" are admitted. Arranged according to this plan it will evidently fulfil its mission.

A Treatise on Diseases of the Nose and its Accessory Cavities. By Greville Macdonald, M.D. Lond., Physician to the Hospital for Diseases of the Throat. Second Edition, 12mo, pp. 369. London and New York: Macmillan & Co. 1892.

The second edition of this work appears within a year from the issue of the first publication. Numerous important additions have been made, emphasizing the author's endeavor to incorporate in his treatise everything worth knowing on the subject. Among the important additions which have been made may be noted those under croupous rhinitis, cysts of the middle turbinated bone, idiopathic rhinorrhœa, nasal asthenia, and a full chapter on nasal neuroses. The subjects are treated on the basis of personal experience of the author, and are consequently viewed from a practical stand-point. While fully appreciating the significance of certain well-recognized pathological conditions of the nasal organs, there is a judicious conservatism regarding many of the so-called radical operative procedures which marks the writer as not only a progressive rhinologist, but a safe operator. His views of the pathology of the different affections are eminently sound, and in keeping with those of the advanced workers in his specialty. The style of writing is pure, terse, and forcible, and gives an additional charm to the work. The wood-cuts are admirably made, and the general typographical excellence of the work is everything that could be desired. As a contribution to this department of surgery the book is destined to keep its well-earned reputation as an authority.

The Science and Art of Midwifery. By William Thompson Lusk, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children, Bellevue Hospital Medical College. New Edition, revised and enlarged. 8vo, pp. 761. New York: D. Appleton & Co. 1892.

From its first appearance Professor Lusk's work became an authority in its department. It has so far maintained this reputation that its fourth edition comes to us within a period that is covered by the first edition of many others. In the present edition there are many evidences of radical change in views of pathology and treatment which were made necessary by recent advances in the obstetric art. Not the least of these teachings have been those referring to judicious antiseptic precautions, especially in connection with those newer and more useful surgical procedures for "complications formerly regarded as beyond the pale of human help." It is needless to say anything more regarding this treatise than that it fully maintains its former reputation as a thoroughly scientific and comprehensive treatise on the subject of which it treats, and that it is destined to keep its place as the leading American system of obstetrics. The scientific reasons for certain procedures are so clearly given and so tersely stated that their practical application to emergencies on hand do not admit of question. The treatise is complete in every way. Its illustrations are numerous and well executed.

The Annual Report of the State Board of Health for New Hampshire, for the Year ending October 31, 1891. 8vo, pp. 271. Concord: I. C. Evans. 1891.

This volume contains several interesting reports, notably those upon the sanitary condition of county almshouses, asylums, and jails, prevention of typhoid fever, the sewerage of New Hampshire towns, and the milk supply.

A Text book on the Practice of Medicine, for the Use of Students and Practitioners. By R. C. M. Page, M.D., Author of a Chart of Physical Signs of Diseases of the Chest, Professor of General Medicine and Diseases of the Chest, New York Polyclinic, etc. 12mo, pp. 568. New York: William Wood & Co. 1892.

It is so much the fashion in these days of epitome to produce small books in place of large ones, and thus omit essentials of principles and detail that the student is naturally prejudiced at attempts in such directions. Professor Page's work is, however, an exception to this rule in every important particular. It fulfils its aim admirably and satisfactorily. Herein are given the results of a long experience in clinical teaching and a thorough appreciation of the needs of the student and practitioner. The arrangement of subjects is simple and comprehensive. Each disease in the domain of internal medicine is treated from the practical stand-points of etiology, pathology, symptomatology, prognosis, and treatment. Especially in the latter has the author succeeded in giving a practical turn to his teachings and in adding a unique value to his work. While his descriptions of lesions and physical signs are accurate and sufficiently full, his therapeutics prove him to be a teacher more than ordinarily qualified to apply his principles to the sound common sense practice of the day. Altogether it is one of the best works of its kind, and is destined to have a large sphere of usefulness when its many excellences as a safe guide-

book are becomingly appreciated. The reader will find many admirable prescriptions scattered through the text, and will feel grateful for many clinical suggestions which are rarely found in a work of this kind.

Outlines of Zoölogy. By J. Arthur Thomson, M.A., F.R.S.E., Lecturer on Zoölogy in the School of Edinburgh. 12mo, pp. 631. New York: D. Appleton & Co. 1892.

This is a very compact and concise volume upon the subject of which it treats, and embodies in its generalization, systematic arrangement, and treatment of detail, everything that can be expected in a comprehensive manual. Tracing as it does the primitive organism of the simple cell to the more complex organizations, it carries the student, by logical and systematic arrangement, through the different classes and types of animal life, giving him an intelligible idea of the evolutionary element that pervades the entire system of development The style is lucid and leaves nothing to be desired in intelligible description or practical demonstration. There are thirty-two full page illustrations, which still further add to the value of the work.

Chirurgische Technik, Ergänzungsband zum Handbuch der Kriegschirurgischen Technik enthaltend die übrigen Operationen. Von Dr. Fr. von Esmarch, Professor der Chirurg. in Kiel, und Dr. E. Kowalzig, vorm. 1. Assistant d. Chirurg. Klinic, mit 520 Holzschnitten. 12mo, pp. 372. Kiel and Leipzig: Lipsius & Tischer. 1892.

This work, on operative surgery, is one of the most practical and comprehensive that has been published for a long time. The arrangement is admirable, the descriptions of the different operations are terse, and yet full enough to act as an intelligible guide to the operating surgeon, while the essential details are enforced in a manner that cannot fail to be impressive. All the newer methods of the advanced school are duly described, and their practical applications, founded on the extensive experience of the authors, are given with an impartiality of relative merit that gives them a unique value. The illustrations are, however, such a leading feature that it would appear amiss not to refer to their peculiar excellence in bringing out the salient points of technique which every operator esteems of such value and importance. To such of our surgical readers as are conversant with the German language this admirable book will be an invaluable addition to their libraries.

Fifteenth Annual Report of the Board of Health of New Jersey, 1891. 8vo, pp. 489. Trenton, N. J.

This "Annual Report" is as usual filled with interesting material for the student of public health. The reports from the different local boards of the State are instructive and suggestive, while the papers on school hygiene, vital statistics, and sewerage are models of their kind.

Traité Pratique de Gynécologie. Par Dr. A. Auvard, Accoucheur des Hôpitaux de Paris. Avec 525 Figures dans le texte, et 12 Planches en couleurs hors texte. Pp. 792. Paris: Octave Doin, diteur, 8 Place de l'Odéon. 1892. (A Practical Treatise on Gynecology. By Dr. A. Auvard, Obstetrician of the Paris Hospitals. With 525 Illustrations in the Text, and 12 additional Colored Plates. Pp. 792. Paris: Octave Doin, Editor, 8 Place de l'Odéon, 1892.)

This new French work is a worthy rival of Pozzi's as regards the freshness and beauty of the illustrations, though it cannot bear comparison with it from a scientific stand point. Although it contains much that is valuable to the specialist, it is too bulky in size and a little too pedantic in some places to become generally popular. We refer particularly to the chapters bearing the high-sounding titles "Abdominopathies Simili-génitales," "Emmenologie," "Genitalite," which in plain English mean simply reflex neuroses, disorders of menstruation, and inflammatory affections of the uterus and adnexa.

The arrangement of subjects is somewhat peculiar, though not without its advantages, the chapter on diagnosis being placed at the end, instead of at the beginning. Chapter IV., on affections of the external genitals (always a favorite subject with French writers), includes a *brochure* on eruption, especially the syphilides, which is beautifully illustrated with no less than seven colored plates. The chapter on inflammation of the uterus, adnexa, and peri-uterine tissues is ingenious and suggestive, the central idea being that septic and specific infection are transmitted along the continuous mucous lining of the genital tract to the peritoneum.

The recognition of seven distinct varieties of metritis, however, only leads to confusion. The section on "Ulcerations of the Cervix" preserves the old errors which we thought had been generally abandoned. The two time-honored plates representing the different forms of laceration of the cervix should be credited to Mundé, not to Mouer. Fig. 8, Plate XII. (by the author), certainly represents a simple erosion, *not* epithelioma. The subject of trachelorrhaphy receives better treatment than in most foreign works. This varied chapter concludes with a description of vaginal hysterectomy as performed by Péau and other French surgeons for the cure of chronic endometritis, salpingitis, and peritonitis, an operation which will never commend itself to American operators, in spite of the fact that Péan is credited with fifty operations without a death. The chapters on uterine and ovarian tumors, on affections of the urinary tract and of the rectum are very good. The chapter on sterility is sufficiently explicit, without entering into those prurient details in which some of our French *confrères* seem to delight. We have no hesitation in commending M. Auvard's book as a worthy example of the progress of modern gynecology. With few exceptions he is clear and concise in his style, and possesses the happy faculty of describing surgical operations briefly and to the point. As an artist he is unrivalled. The most valuable feature of the book is the number and originality of the illustrations. Every subject is illustrated by ingenious diagrams, which render details unnecessary. This is a new departure which deserves especial commendation.

Transactions of the American Orthopedic Association. Fifth Session. Vol. IV. 8vo, pp. 403. Philadelphia. 1891.

This volume is a creditable one in every respect, contains a number of very valuable and practical papers, with fine illustrations, and will prove of great value to the student of this growing specialty.

Miner's New Complete Obstetric Record, Combining with the Usual Record all desirable Medical Statistics, together with a Medical History of the Pregnancy and of the Life of the Child, whenever these are Medically Noticeable. Pp. 124. Ann Arbor, Mich.: Joel A. Miner.

This is a book which will prove most convenient for the general practitioner, since it includes the necessary memoranda within a remarkably small space. Each page provides for the recording of seven births, or 868 in the entire book, so that it will last almost a lifetime. We commend it as one of the handiest little record-books of the kind which we have seen.

Professor Emil Fischer, of Würzburg, is to have a new chemical laboratory, the plans of which have recently been prepared. The estimated cost of the building is $150,000.

For Basedow's Disease, a homœopathic physician recommends nux moschata (nutmeg).

Society Reports.

American Medical Association.

FORTY THIRD ANNUAL MEETING.

Held in Detroit, Mich., Tuesday, Wednesday, Thursday, and Friday, June 7, 8, 9, and 10, 1892.

SECTION IN PRACTICE OF MEDICINE.

THIRD DAY, THURSDAY, JUNE 9TH.

The Genesis of Pneumonia.—This was the title of a paper read by DR. W. W. PENNELL, of Fredericktown, O. The great question is as to whether pneumonia is a general fever or a local disease. Bacteria, the writer believes, play only a secondary part as a causative factor. The inflammation produced experimentally by pure cultures of this germ differs from that of the primary cultures. There is not an exact analogy with the so-called specific diseases, and our treatment is not such as to carry out this view. The infectious character of the disease is not observed in country districts. As against this specific character are the following arguments: 1. More than one germ is found. 2. The patients are liable to subsequent attacks of the disease. 3. It is not contagious. 4. There are no prodromata. 5. There are no sequelæ as in typhoid fever. 6. There is a distinct crisis unless peri-infiltration or abscess results. If the exudate can be kept in the vesicles—in quarantine as it were—it will lose its power to infect. 7. Antiphlogistic treatment will often abort the disease.

The causes of the disease may be enumerated as follows: 1. Cold, merely, is not a cause. 2. Continued exposure and exertion, with wide thermometric range. 3. The "dust chill," often felt by farmers after threshing grain. 4. As a sequel of lowered vitality due to vicious habits, especially alcohol and venery. 5. Inhalation of dust and foreign bodies. 6. Bad general hygiene, poor sanitation, enervating habits, etc. 7. Some persons and families have a predisposition. 8. No sex or age is exempt.

The three factors, then, in pneumonia are a predisposition, a loss or lack of normal tissue resistance, and an exciting cause.

DR. BAILEY, of Kentucky, believed that the typical history points to a definite cause. The fever terminates irrespective or independently of the local condition. The physical signs show more complete infiltration the day after the crisis of the disease than the day before.

The Cardiac Indications in the Treatment of Pneumonia.—DR. J. M. ANDERS, of Philadelphia, read a paper on this subject. The causes of this cardiac weakness may be threefold. We may have an absorption of toxic ptomaïnes as a result of the disease process, with a weakening of the heart-muscle. There may be pulmonary obstruction, produced by the presence of the exudate acting as a local barrier to the integrity of the circulation. Finally, we may have the formation of cardiac thrombi, which are found in the right ventricle. The latter becomes dilated and thus there is failure of heart-power.

The signs of the muscular degeneration appear as a feebleness and shortening of the first apex-sound, and a similar condition of the aortic second sound. The pulmonary second sound may be accentuated, at least temporarily. Here alcohol in moderate doses is indicated. It stimulates the cardiac ganglia, the respiration, and the nerve-centres. It should be followed up by strychnine, which remedy has a well-known stimulating effect upon the cardio-pulmonary apparatus. Digitalis is to be used very cautiously, if at all. It may, by lengthening the period of diastole, favor in some cases the nutrition of the heart-muscle.

For the local engorgement cups, leeches, and especially ice-bags, are profitable. The writer distinctly deprecates the use of veratrum, aconite, antimony, and similar cardiac sedatives. To control any cardiac overaction morphine is the remedy *par excellence*. Occasionally, but rarely, is venesection necessary. If there is much consolidation, with a good heart, veratrum can be cautiously exhibited.

In regard to the temperature, our aim should be to reduce it without reducing heart-force. A fever of 104° F. needs no antipyretic measures. Beyond that limit we are to employ cold sponging, and from sixteen to twenty grains of quinine daily. The coal-tar products come under the ban, for they are cardiac depressants, just what we wish to avoid.

To meet the second indication, viz., the obstructed pulmonary circulation, we must remember, first of all, that the consolidation of a single lobe does not greatly interfere with breathing; but if we notice that the pulmonary second sound is losing its sharp accentuation, and is gradually becoming weaker, we have a double duty to perform. We must increase the power of the heart and deplete the lung. For this purpose nitrites of any sort alone are useless. Cups and venesection alone prove adequate. Here we find an indication for the employment of digitalis combined with nitro-glycerine.

The formation of cardiac thrombi is probably more frequent than is commonly believed, and is often associated with the other two factors. In this disease the fibrin-forming elements are increased. The signs of this condition are not difficult to recognize. The impulse is irregular. The area of dulness runs beyond the right of the sternum. There is a systolic bruit heard at the xiphoid cartilage, transmitted up and to the left. The ammonium salts are the only remedy that we have with which to affect the fluidity of the blood. These should be freely administered.

DR. BAILEY believed that phenacetin could be safely used as an antipyretic in pneumonia. It was as efficient as external applications of cold water, and no more depressing to the heart. He did not believe in blood-letting; never saw a case of pneumonia in which, in his opinion, venesection was indicated. He doubted the power of the ammonia compounds to dissolve clots already existing, but thought that the formation of the latter might thereby be prevented.

DR. TRUAX, of New York, favored venesection.

DR. HERRICK, of Cleveland, thought that the antecedents of pneumonia were to be found in perverted action of the abdominal organs.

DR. DIDAMA, of Syracuse, N. Y., thought that venesection was good for those cases in which there was extreme cyanosis, with a watery, prune-juice expectoration.

DR. MUSSER, of Cincinnati, regarded the disease as specific and infectious. The three remedial agents required were, in his judgment, cold, venesection, and rest. To combat the inflammation the first two are employed. The indications for venesection are, the physical signs, the spreading of the hepatization to new areas of lung tissue, and the altered relations between pulse, respiration, and temperature. Strychnine might be used hypodermatically. Digitalis was not of much service. Alcohol and ammonia (the former as champagne) held a high place in his estimation. For the rest and freedom from worry nothing approached morphine in value.

The paper was further discussed by Drs. Greenway, of Kentucky, and Pennell, of Ohio.

Darwinianism and Disease.—DR. HUTCHINSON, of Des Moines, Ia., read a paper on this subject. The leading idea was that the majority, if not all, of pathological processes are merely illustrations of various phases of evolution, and at times of benefit to animal cells and to the body at large. Reversion of type often takes place, and is followed by corresponding disadvantages. Numerous illustrations were given showing the practical application of these views to the recognition of apparent deformities in the body structure and anomalies in disease.

Tissue-group reversions might be either caseous, calca-

reous, fatty, or fibroid. These might all be characterized as vital action gone wrong. Reproductive reversions were tubercle, gumma, benign growths, malignant growths, and hypertrophy. If the malignant reversion occurred in connective tissue we had a sarcoma, with its round or spindle-shaped cells; if in the glandular or epithelial layers, a carcinoma, which might be described as "a parody on glandular tissue."

From all this we must believe that there is another factor in disease than the germ. Lowered vitality is concerned therein, and our treatment should be to improve nutrition and so elevate vitality that the normal processes of bodily evolution shall go on undisturbed.

On the Analogy Between Acute and Idiopathic Pleuritis and Acute Artieular Rheumatism.—A paper with this title was read by Dr. E. L. Shirley, of Detroit. The pleural as well as the synovial and other serous membranes spring from the same primordial layer—the mesoblast—and ultimately develop into the same endothelial lining. Hence they would naturally be alike affected by any pathological process. On the other hand, there is a correspondence between the phenomena, characteristics, and general clinical history of the two diseases. The presence of a pleuritic complication in rheumatism may be suspected when we have fugitive pains in the side, transient respiratory embarrassment, or sudden exacerbations of temperature unattended by any increase in joint disturbance. Often these appearances are regarded as due to pericarditis or endocarditis, when they are really of pleuritic origin.

Furthermore, the results of treatment are corroborative of the view expressed as to the identity of the two affections. Sodium salicylate is the remedy *par excellence* for this condition of the pleura.

Dr. Stockton, of Buffalo, spoke of the causes of pleurisy associated with, and preceded by, articular rheumatism. The former trouble may be worse than the joint affection.

Dr. Atkinson, of Baltimore, thought that while the relation between the two diseases might be true in theory, the revelations of the dead house negative the idea of there being any great amount of pleurisy in these rheumatic cases. Most of our cases of pleurisy cannot be explained on the rheumatic theory. In pericarditis we find pleuro-pericardial sounds which may be mistaken for a simple pleurisy.

Dr. Collins, of London, Ontario, remarked that sodium salicylate will often cure inflammation in any serous membrane. The remedy can be regarded as a true germicide.

Additional Evidences of the Value of Forced Respiration; Fell Method in Opium Narcosis.—Dr. Geo. E. Fell, of Buffalo, read a paper on this subject. In addition to the nineteen cases previously reported, the author gave brief notes of five additional ones. He thought that this method of resuscitation would be applicable to drowning or asphyxia from any cause. His apparatus, with the face mask, was exhibited, and its method of use demonstrated.

The following papers were announced, but not read: "Epilepsy," by Dr. M. M. Leahy, of Chicago; "A Case of Fermentative Poisoning," by Dr. J. T. Axtell, of Hartford, Conn.; "Conditions of the Heart and Pulse in Phthisis," by Dr. N. S. Davis, Jr., of Chicago; "Pneumonia as a Blood Disease," by Dr. Ephraim Cutter, of New York; "Diet and Regimen in Pulmonary Consumption," by Dr. Edward F. Wells, of Chicago, Ill.; "A Clinical Note on Rotheln: Period of Incubation," by Dr. Chas. A. Hough, of Lebanon, O.; "Kidney Colic," by Dr. Ferdinand King, of New York; "Europhen: with Clinical Reference to Europhen and Europhen-Aristol," by Dr. John V. Shoemaker, of Philadelphia, Pa.; "A Few Notes on the Mechanical Therapeutics of Osseous and Medullary Lesions of the Spine," by Dr. Thomas H. Manly, of New York; "Phenacetine, with Special Reference to its Effect in the Nervous Sequelæ of Grippe," by Dr. W. F. Hutchinson, of Providence, R. I.

Election of Officers.—*Chairman*, Dr. Charles Stockton, of Buffalo, N. Y.; *Secretary*, Dr. George Webster, of Chicago, Ill.; *Executive Committee*, Drs. Hobart A. Hare, of Philadelphia; Isaac Atkinson, of Baltimore; N. S. Davis, Jr., of Chicago.

SECTION ON SURGERY AND ANATOMY.

Third Day, Thursday, June 9th.

Is Amputation ever Indicated in Coxitis?—Dr. Herman Mynter, of Buffalo, N. Y., stated that sixty five cases of amputation had been reported on account of old neglected cases of hip-joint diseases. Primary amputation, of course, is never indicated, and secondary amputation, which usually has been done on account either of recurrent caries or diffuse suppuration, may be avoided by due care in removing all diseased tissues of bone and synovial membrane. In most cases, probably, the recurrence of the caries is less a recurrence than a continuation in the form of a chronic osteomyelitis in the shaft of the femur, extending all the way down to the lower epiphysis. In two cases of excision recently performed, the author made a counter-opening with the chisel, on the outer side of the femur, just above the lower epiphysis, cleaned out the central cavity of the femur with a long, sharp spoon, and introduced a strip of iodoform gauze through the central canal. This was replaced once a week for five weeks under narcosis, and then omitted, as the bone looked perfectly healthy, and the wounds then healed rapidly. Reference was made to similar operations made by Poore, of New York.

Dr. John Ridlon, of Chicago, complimented the author on his exceptionally good results, and thought that the average excision at the hip-joint gave a much less good result than that obtained by mechanical treatment. In cases of osteomyelitis of the shaft of the femur the operation done in the two cases reported was clearly indicated before doing an amputation. In cases, however, where osteomyelitis of the shaft was not present, he did not think excision was ever demanded except as a life-saving measure, when an amputation might prove a safer operation. As to the scooping out of cheesy or suppurating foci in the head and neck of the bone, he knew of no way by which the cheesy focus could be located with certainty, nor could it be known that there was not more than one focus present; and operation without a clear indication of the condition for which the operation was made is hardly a scientific procedure. The non-operative treatment of hip disease gives so many perfect results when intelligently and faithfully carried out that he was not given to advise operation so long as the local and general symptoms progressed favorably.

Dr. Edmund Andrews, of Chicago, said that there were often several foci of disease, as in one of the specimens presented by Dr. Mynter, and that there was no certainty in any case that an operation would remove all the foci. After suppuration, however, excision would be found to be the shortest and easiest way out of the trouble.

The Cremasteric Reflexes in Varicocele.—Dr. T. A. McGraw, of Detroit, said that every man would have a varicocele if it were not that certain muscles, especially the cremaster, supported the spermatic veins, and by an intermittent contraction forced the blood along. The abdominal muscles aid in this action. Any defective muscular action, whether due to congenital, paralytic, or acquired weakness, especially in early life, results in distention of the veins and ultimate varicocele. Later in life the walls of the veins become thicker and stronger, when a defect in muscular action is much less felt. He had rarely found scrotal hernia associated with distention of the scrotal veins; and he was of the opinion that a subject liable to inguinal hernia was not liable to varicocele. Again, the causes that tend to the development of hæmorrhoids rarely, if ever, appear as causative of varicocele. Deficiency in cremasteric reflexes is almost al-

ways found in cases of varicocele, and it would appear that varicocele is due to the defective action of the cremaster muscle.

Dr. W. B. DeGarmo, of New York, said that hernia had no special bearing on the causation of varicocele; nor has the wearing of ill-fitting trusses making pressure on the veins appeared to be causative. It is very rare in later life, and rarely, if ever, caused by a strain.

Experimental Research on the Implantation of the Ureters into the Rectum.—Dr. R. Harvey Reed, of Mansfield, O., prefaced his paper by saying: "It has been the object of the author of this paper to demonstrate, by experimental research, the possibility of relieving many of the grave disorders of the bladder, in which the urine constitutes a permanent source of irritation, by diverting the course of the urine from the bladder into the rectum; also to avoid the necessity of performing a nephrectomy in laparotomies for neoplasms, in which one or both of the ureters may be involved by implanting the ureter into the rectum." After reporting numerous experiments and their results, and showing specimens of the same, together with photographs, the doctor concluded his paper as follows:

"1. That the unilateral implantation of the ureter into the rectum is a possible and practical surgical procedure.

"2. That the bilateral implantations of the vasa deferentia into the rectum is not followed with any serious or detrimental results, further than rendering the dog sterile.

"3. That the simultaneous implantation of both ureters into the rectum is still a questionable surgical procedure, as shown by the experiments made thus far on the dog, and also by Kuster's double implantation of the ureters in man.

"4. That the presence of urine with the fæces in the rectum does not produce pathological irritation of the latter, but that the rectum will readily accommodate itself to its presence.

"5. That the passing of frequent liquid stools cannot be depended upon as resulting from implantation of the ureters into the rectum, and the presence of urine in that receptacle.

"6. That these experiments have suggested the probability of a portion of the CO_2 of the urine, being absorbed by the rectum, leaving the salts, etc., of the same to be eliminated from the economy with the fæces.

"7. That the ligation of one ureter, and the consequent production of hydronephrosis, is not necessarily followed by inflammation and destruction of the wall of the ureter or the substance of the kidney, and suggests one of two things: either the arrest of the secreting powers of the kidney, or the reversal of the natural physiological process of elimination for those of absorption."

After giving the conclusions, he closed the paper with the following practical observations: "We firmly believe that these experiments have shown, without much doubt, the practical utility of unilateral implantations of the ureter in cases where either one of the ureters is involved, from the result of adhesions, from ovarian or other tumors of the abdominal cavity; and that it is a safer procedure to resort to the implantation of the ureter into the rectum than to perform a nephrectomy, which has been the custom heretofore. We also believe (and intend at some future time to endeavor to demonstrate by a continuation of these experiments) that bilateral implantations can be made successful by the introduction of one ureter at a time, giving the first one time to recover before the second one is implanted. If this can be accomplished, it will enable us, in cases of disease of the bladder, to divert the urine from that organ to the rectum, and thus either relieve the disease, or, if necessary, extirpate the bladder, which at present cannot be done without bringing the ureter out through the perineum with all the horrors of such an unpleasant condition, which is only excelled by an artificial anus.

"If, however, we have only succeeded in preventing the necessity of a nephrectomy by these experiments, where one or the other ureter is involved by some pathological difficulty in the abdominal cavity, we will feel justified in the expenditure of the time and trouble these experiments have necessitated."

Visceral Phlebotomy.—The Secretary read a paper with the above title, by Dr. George Harley, of London, England. Cases were reported in which a trocar had been plunged into the liver for purposes of depletion, and it was advised that every suitably situated internal organ when congested should be thus directly depleted, in place of cupping and leeching.

Advances in Antiseptic Surgery.—Dr. F. J. Thornbury, of Buffalo, N. Y., said that wound infection through the air was very much less common than through contact. He then went on to describe methods of purifying the hands of the operator and of the skin of the patient. Instruments should be boiled in a solution of soda, and apparatus was shown for this purpose. Dressings should be disinfected by steam (apparatus demonstrated) and applied dry and kept dry in so far as it is possible, since dryness is antagonistic to germ development.

Ligature of the Hypogastric Artery.—Dr. Christian Fenger, of Chicago, gave a synopsis of two cases in which he had tied the internal iliac artery: in one case for hemorrhage into an abscess, and in the other for gluteal abscess. He then went on to discuss *in extenso* the literature and the statistics of the subject, with the prognosis, etc.

Operative Procedures on the Base of the Brain.—Dr. Ernest Laplace, of Philadelphia, reported three series of experiments upon dogs. In the first series the anterior fossa was the seat of operation, in the second the middle fossa, and in the third the posterior fossa.

The risk from these operations appears to be from shock, which is controlled by one-twentieth grain doses of strychnia; from hemorrhage, controlled by forceps or packing with iodoform gauze; and lastly, from deficient drainage. The base of the brain may be investigated and clots and spiculæ of bone removed by a flexible instrument made from platinum wire in the shape of a miniature egg-beater. A case, already published, was briefly referred to where he had trephined and removed a clot from the anterior fossa.

Dr. Edmund Andrews, of Chicago, referred to two cases in which he had trephined the base of the skull to remove the semilunar ganglion; and also to the work of Rose and Horsley, of London.

Gun-shot Wounds of the Cerebrum.—Dr. C. E. Ruth, of Muscatine, Ia., reported a case and experiments. He said that the line pursued by the ball through the brain was usually a straight line, but that it did not bear any definite relation to direction from which the shot was fired, and after passing through the brain it seldom rebounds sufficiently to re-enter the brain to any extent. In searching for the track of the ball, he uses a probe with a hemispherical porcelain tip and a slender aluminum shaft. A trephine not less than three-fourths of an inch in diameter should be used. He made the following summary: 1. A ball can be followed in its course through the brain. 2. Having been followed to the point of impact on the opposite side of the skull, a trephine disk should be removed, drainage be established, and ball removed if possible. 3. That the probe is best which gives the greatest resistance to penetration with the least possible lateral friction on its shaft by the collapsed canal. 4. That hemispherical-front porcelain tip and aluminum shaft answer the indications for lead detection (resistance, if of proper size), weight, etc., required in a probe, better than anything else. 5. That one intending to follow balls through the brain should thoroughly familiarize himself with the resistance the normal brain offers to penetration by the probe he expects to use, that he may know when he is applying force within safe limits. 6. That he should frequently grasp and remove

balls and pieces of bone with the forceps of his choice on the cadaver before attempting it upon the living subject.

The Cosmetic Surgery of the Nose.—Dr. John B. Roberts, of Philadelphia, called attention to the ignorance of the non-professional public on this subject, which leads many sufferers to resign themselves to unsightly deformity. A plea was made that physicians discourage the correction of such disfigurements and undertake operative measures for their relief. Slight operations will often effect an astonishing change in the personal appearance of the patient, and even extensive operations are devoid of danger. No marked scarring occurs if such operations are properly done. Oblique incisions, antiseptic union, and the location of the incisions in grooves of the skin make external wounds unnoticeable. In addition, many of the operations are done within the nose, which is reached by the nostrils or through the mouth under the upper lip. No cosmetic surgeon will be successful who does not recollect the frequency of tertiary syphilis of the nose. He may undertake to incise syphilitic gummy tumors and allow destruction of the nose from syphilitic ulceration, if its frequent occurrence is not constantly in mind. All doubtful cases should be tested with large doses of mercury and iodide of potassium. Then followed a description of the various deformities of the nose that are successfully treated, and of the means which the surgeon may employ for their correction. The angular nose, the Jewish nose, the tubulous nose, and all sorts of twisted and crooked noses were said to be amenable to properly directed operation. The correction of the sunken and distorted organs due to syphilis was a prominent subject of consideration, and methods of inserting metallic bridges to substitute the bony bridge were mentioned.

A Few Suggestions on the Diagnosis and Treatment of Lupus.—Dr. William Thomas Corlett, of Cleveland, O., said that lupus was regarded as a local tuberculosis, identical in histological structure with tuberculosis of the internal organs, and due to the bacillus tuberculosis. The differential diagnosis of lupus erythematosus, lupus vulgaris, and lupus verrucosus were then taken up seriatim. The first was often confounded with erythema, rosacea, eczema, psoriasis, and syphilis. Lupus vulgaris was more pronounced, therefore less liable to be mistaken for anything else, but it often resembles the late manifestations of syphilis, and when confined to a small area might be mistaken for epithelioma.

As accessory to treatment in all forms of lupus, he advised a diet rich in hydrocarbons. The internal treatment consisted of cod liver oil, creosote, and iodine. The mode of giving creosote was important; from one to two minims were given in capsule every two hours, and the dose gradually increased to three minims. Mild cases might yield to this alone, but in most cases it was necessary to attack the disease *in situ*. He recommended as local applications, sulphur, ichthyol, and the twenty per cent. oleate of mercury. The most efficient means was scarification, followed by the emplastrum vigo cum mercurio; the scarification to be repeated at intervals of a few days until a cure was complete. In the treatment of lupus vulgaris even more radical means were resorted to. Under chloroform the lupus tubercles were thoroughly scooped out with a Volkmann's spoon, the excavations cleansed with a 1 to 1,000 bichloride solution, and the parts covered with pyrogallic acid. After a few days the acid is replaced by a mercurial plaster until resolution takes place. At times the pain, subsequent inflammation, and constitutional disturbance are too severe, when recourse may be had to milder escharotics, as creosote or carbolic acid. Several operations are usually required before the disease is eradicated.

Forced Respiration, per Face mask and Tracheotomy in Diphtheria.—Dr. George E. Fell, of Buffalo, N. Y., called attention to an interesting case of diphtheria occurring in a family of four young children, who were all taken down with the disease. The first child was given home treatment and recovered, while the second, under similar treatment, without the parents knowing the seriousness of the disease, passed to a rapidly fatal condition. Dr. Fell was called and proceeded to perform the operation of tracheotomy. The patient, a boy of seven years, becoming unconscious from cyanosis, it was unnecessary to give an anæsthetic. Before the operation had proceeded far the dilatation of asphyxia was evidenced by the pupils dilating rapidly. Had it not been for the forced-respiration apparatus which had been provided, the patient would have died immediately after the initial incision, as it was found necessary before the operation of tracheotomy was completed to apply the forced respiration apparatus some five or six times when auto respiration ceased. Following this, forced respiration was kept up per tracheotomy tube for some time before the patient became conscious. The peroxide of hydrogen was used, with gratifying results, freely in the mouth and nasal cavities, and also to the tracheal incision. Many times when dyspnœa became great the liquefaction of the membrane in the bronchial incision was brought about by it so as to relieve the patient. In some instauces when this would not relieve the patient forced respiration through the tracheotomy tube overcame the cyanosis and enabled the patient to breathe for himself for some period of time. The exudation, however, continuing to interfere with the respiratory process, the patient succumbed some sixty hours after the operation was made. The case illustrates the value of forced respiration per face-mask in conditions where membranous exudates interfere with respiration, and in membranous croup and diphtheria; and also the value of peroxide of hydrogen in liquefying the exudates in such conditions.

The Powerful Effects of Sulfonal in Arresting the Cramps of Fractured Limbs and other Reflex Spasms.—Dr. Edmund Andrews, of Chicago, reported a case of very painful cramps in a recently fractured femur, in which fifteen-grain doses gave complete relief. The action of the drug is somewhat slow, and it should be given in from six to eight-grain doses three times a day, or in a single large dose two or three hours before the sleeping time. The anti-spasmodic power is more useful than the sleep-producing power.

Joint Amputations.—Dr. S. L. McCurdy, of Dennison, O., quoted Dr. Allis in a paper before the Pennsylvania State Medical Society: "Don't amputate through the joint; go above or below it." Truax, the instrument-maker, insists upon the same thing.

The paper desired to prove that joint amputations make the best stumps, and that no one is justified in going above a joint when a disarticulation can be made. Human flesh should not be sacrificed on account of lack of ingenuity on the part of the mechanic. He claimed that the normal joint surfaces, covered with abundant flap, with the scar posteriorly at the knee and the Symes at the ankle, make more desirable stumps than those formed by a cut made through the shafts of the bones. Artificial limb manufacturers can and do make legs for joint amputations more durable and comfortable to the patient than at any point above the joint.

He insisted upon the bearings of artificial limbs being upon, 1, ankle, as in a Symes; 2, around the knee; 3, condyles of femur; 4, perinæum by the use of the Thomas ring. Artificial limbs were presented to show that limbs are made for disarticulations.

The writer thought that the future operation will be a Chopart or Hayes, with tenotomy of the tendo Achillis and anchylosis induced in the tarsal and tarso-tibial articulations, thus saving the foot.

Dr. King, of Missouri, in a very large experience in military and railroad surgery had found that amputations through the joints cause the most trouble and return the most frequently for advice. The hollowed-out willow limbs are always the best; they last the longest and require the least repairs; and in a hollowed-out willow limb it is impossible to fit any except a conical

stump satisfactorily. Bulbous stumps, as recommended by Dr. McCurdy, demand leather lacings, which require early and frequent repairs and renewals, and the joints at either side of the thigh portion make a less strong and less comely limb than the ordinary artificial leg joint.

Dr. Craig, of Pennsylvania, said that no patient ever walked gracefully after the tarsus had been removed, and that if this portion had to be removed he preferred to go to the point of election, five inches below the knee.

Fourth Day, Friday, June 10th.

Air in the Veins.—Dr. Edward Martin, of Philadelphia, reported experimental researches. He had found it impossible for air to be sucked into the veins when they were exposed and cut in the neck of the dog, but that they must be held open mechanically to admit its entrance. In dogs the entrance of a few bubbles was of no moment, but the entrance of a considerable quantity killed the animal. In monkeys, however, the entrance of even a small quantity killed within thirty seconds. In the human subject, the accidents which had befallen the writer led him to believe that air is not readily sucked into the veins, but does readily enter the cellular tissue, in which case no dangerous symptoms supervene.

Report of Case of Talipes Equino Varus.—Dr. B. Merrill Ricketts, of Cincinnati, reported a case of congenital deformity. The foot was turned straight backward so that the weight of the body came directly upon the astragalus. This caused the plantar surface of the foot to be thrown upward to such a degree that the under surface of the toes was the only part that touched the ground while standing erect. An incision was made from the lower end of the fibula in the direction of the lower end of the tibia, which exposed the ligaments and tendons of the joint. None of these tissues were divided, but were crowded aside, the more easily to remove the astragalus, which was found greatly deformed, having lost its normal outlines. An attempt was then made to bring the toes forward to their normal position, which was not very successful. The little remaining part of the Achilles tendon being very dense, it was found necessary to divide all the tissues posteriorly before the foot could be brought forward to its normal position. The plantar fascia was found to be so dense that it had to be divided in order that the foot could remain in its normal position. The operation was made under hot filtered water irrigation with dressing of same character.

Drainage was not provided for in this case, but the writer would not fail to use it again, as regret had followed every case where he had failed to make this provision. The result was in every way satisfactory.

Dr. Ridlon, of Chicago, said that the adherence to any one method of treatment in these cases argued a lack of experience. As much or as little must be done as the individual case demands, and there are a certain number of cases where full flexion of the foot cannot be gained without removal of the astragalus. He then referred to a case which he had treated successively by manipulation and Barwell dressing, tin splint, plaster-of-Paris, Thomas's wrench, and an iron brace, tenotomy, Judson's shoe, Phelps's open incision, and plaster dressings, followed by retentive brace, but after each there had been a relapse. When the astragalus had been removed it was found that its tibial articular surface, instead of being convex and looking directly upward, was plane and looked backward and upward at an angle of forty-five degrees with the horizon.

Dr. R. H. Sayre, of New York, had never met with a case where removal of the astragalus had been necessary, nor had he met with any congenital cases in children, or even in adults, that required any bone-cutting operation.

Amputation of Scrotum, and Circumcision.—Dr. B. Merrill Ricketts, of Cincinnati, reported a case :

Mr. F. P——, aged twenty two, white, American, well-developed both mentally and physicially ; height, 5 feet 8 inches ; weight, 130 pounds ; brown eyes, dark brown hair, and of a nervous temperament. Had not syphilitic taint, nor predisposition to tuberculosis. Had moderate habits. He came with the statement that he had consulted nearly all of the leading surgeons and dermatologists of this country without obtaining a diagnosis or any encouragement from surgical interference.

Examination showed that his scrotum was much thickened, as was also the prepuce in its normal size. The parts were covered with papillomatous growth varying in size from pin-heads to that of a large pear, with also an occasional angeioma. The right leg was also covered with these growths. A bandage had been worn on the leg for a long time. Upon removal of this bandage the leg would immediately swell to twice its normal size, with the characteristic glistening appearance. Should these growths be disturbed or the skin punctured, there would follow an exudation of lymph, which would flow continuously till from five to thirty ounces would have escaped. This fluid was the color and consistency of thin cream slightly tinged with blood here and there. It was bitter and crystallized on evaporation.

He gave a history of having, at the age of eighteen months, an abscess in the right groin, from which dated his trouble. Every year he would have from three to four chills, followed by a rapid rise in temperature, ranging from 103° F. to 104.2° F., lasting from twenty-four to forty-eight hours. These attacks were preceded by an enlargement of the limb, loss of appetite, eyes glassy, mind inactive, bowels constipated, and great tenderness in and about the right iliac fossa. The glands in this region were greatly enlarged ; circumcision and scrotomy were advised and readily consented to. The operation of circumcision was first made, with the understanding that should it be followed by any bad symptoms, I would not operate on the scrotum. The ordinary operation for circumcision was done and no bad symptoms appeared, and in two months afterward the patient presented himself for the second operation, which was made without any difficulty. During the following year he had but two or three chills, followed by fever. He gained in flesh, and felt entirely satisfied with the operation.

The operation was made not so much to cure the patient as to relieve him.

Neurectomy of the Popliteal Sciatic Nerve for Painful Neuroma as the Result of Gun-shot Injury.—Dr. B. Merrill Ricketts, of Cincinnati, reported the case :

Mr. M——, aged twenty-seven, a tinner by trade, consulted him on August 14, 1891, with a history of having been shot two years previously through the leg, and that he had suffered excruciatingly ever since. Also that he had consulted several physicians without obtaining any permanent relief, and that by their advice he became a morphine taker. He finally reached the maximum of fifteen grains daily, hypodermically, which was verified by the appearance of the pigmentary spots on the legs where the needle had been inserted.

Examination showed that the ball (.38 calibre) had passed obliquely through the left leg to the inner side, three or four inches above the condyle anterior to the hamstring of the biceps, passing upward at an angle of forty-five degrees, coming out about the middle of the thigh externally. The patient stated that when shot he had the sensation in his toes, and not at the real site of injury. He had his shoe removed, expecting to find the injury in his foot, but was quite surprised to find it higher up in the leg. Within an hour after the injury the pain was equally distributed over the foot and leg below the knee.

At the operation the nerve was found to be enlarged to three times its normal size for a distance of 1½ inch, and that the nerve was divided much higher up in this case than usual. This was fortunate, for had it been normal both branches would have been divided. The internal branch was the injured one. The external was found to be adherent to it for the distance of three inches. A section was made 1¾ inch long including the

entire enlargement. The leg was flexed when the section was made, and was retained in this position by means of straps. The pain gradually subsided. The morphine was withdrawn and small doses of bromide and chloral were used instead. After the twelfth day he was allowed to be up and around on crutches. He left the hospital on the twenty-second day.

I heard from him recently, and find that he is free from all pain and the morphine habit.

Methods of Operating in Hernia.—Dr. H. O. Marcy, of Boston, then illustrated with the stereopticon a large number of dissections for hernia, taken from the writings of both ancient and modern surgeons, and explained the same.

Treatment of Compound Fractures.—Dr. W. H. Myers, of Fort Wayne, Ind., said that the chief indications were to arrest the hemorrhage; to render the wound aseptic; to return the bones to their normal position; and to so dress the wound as to retain position, prevent infection, or if already infected, to render it aseptic. No drainage should be used, and rarely any sutures. Perfect rest must be maintained, absence of tension, and an aseptic condition.

Correspondence.

CONCERNING A NEW FLEXIBLE ELECTRODE.

To the Editor of the Medical Record.

Sir: The elastic electrode described as a novelty by my friend Dr. Lapthorn Smith, in the Record of June 11th, page 676, is so excellent and simple that one cannot blame him for discovering it, in spite of the fact that it was previously described by Buckmaster and F. H. Martin. A similar instrument has been devised and described by myself out of a catheter for use in applications to the enlarged prostate. But the difficulty with all wire-wound, flexible-bougie electrodes is in keeping them aseptic. The rubber or composition around which the wire is wound will not stand the ordinary antiseptics, some even not standing continuous immersion in water, and I am doubtful about the efficacy of the soap and water and glycerine recommended by Dr. Smith. A more serviceable instrument is the spiral platinum intra-uterine electrode frequently described by me, made by Flemming, which is indestructible and capable of absolute disinfection in the spirit flame. The tip may be insulated, either temporarily or permanently, by fusing hard rubber upon it.

Very truly yours,

G. Betton Massey, M.D.

SO-CALLED MALARIAL HÆMOGLOBINURIA.

To the Editor of the Medical Record.

Sir: I have read in the Record of June 4th the discussion, in the American Association of Physicians, on the paper of Dr. Hare on "Malarial Hæmaturia or Hæmoglobinuria." Some of the gentlemen evidently mistook hæmaturia, which is a symptom of many diseases, for the well-marked pathological entity variously denominated "malarial hæmaturia," "hæmoglobinuria," "swamp fever," and "black jaundice."

Malarial hæmoglobinuria (I call it so to prevent confusion with hæmaturia), as it prevails in this section (the Mississippi Yazoo Delta), is always a grave disease, the mortality, as I have observed, falling but little below fifty per cent. It has as distinct a clinical history as croupous pneumonia, and it would be as reasonable to say that the latter disease could be induced by the administration of quinine as the former.

Its pathology has not received the attention that it deserves, but it is certainly not a hæmaturia. The urine contains no normal blood-cells except in cases of the severest type, when actual hemorrhage occurs from renal congestion due to increased functional activity required of these organs in eliminating the necrosed blood-disks from the general circulation. Quinia induces more or less congestion of the kidneys, and it would be especially liable to do so when, as in this disease, the organs are much weakened by the strain placed upon them, the blood being at the same time much impaired by the progress of the corpuscular disintegration. These hemorrhages are rarely ever serious. The chief indication for the administration of quinine is the chills which occur in the course of the disease. These, when closely studied, are found to differ from the chills of malaria in several particulars, viz., the subjective symptoms of cold and discomfort are much more marked in hæmoglobinuria, while the same symptoms objectively are slight. They have not the clock-like periodicity, occurring usually at extremely irregular intervals. These chills (rigors) are not followed by marked increase in pyrexia. There is no evidence, pathological or clinical, that this "necræmia" is malarial at all, there being just the same evidence that yellow fever is malarial, viz., both diseases occur in sections where malaria is prevalent and both are usually ushered in with a chill.

To conclude. In my opinion the sole indication for quinine in this disease is in those exceptional cases where the malarial symptoms are marked. At other times it is contraindicated and positively injurious.

Isaac J. Jones, M.D.

Benoit, Miss.

A FECUND FAMILY.

To the Editor of the Medical Record.

Sir: Now that the report of cases of marvellous fecundity seems to be in order, I beg to contribute from my case-book the following somewhat incomplete, but wonderful record. May, 1886, I attended Mrs. S——, aged twenty, in confinement. She was delivered of twins. She first menstruated when eleven years of age. Was married at thirteen. Had one child ten months later. Had two miscarriages, one of which was of twins and one child at term; numbering seven children in seven years. Not a very unusual history, but that of her mother and aunt's is. Her mother, who died when thirty-five years of age, had eleven children in five labors—twins four times and triplets once. One aunt had twins once, and was the mother of twenty-one children. One cousin, daughter of my patient's mother's sister, had twins once. My patient had five aunts, sisters of her mother, all living and all widows.

Respectfully yours,

Edward A. Ayres, M.D.

The Trade in Deformity.—There are at present in Paris some twenty *culs-de-jatte*, or beggars without legs, whose condition has been brought about not by nature but by art. In Spain there are wretches who buy children (generally selecting the infirm, deformed, or idiotic) from their parents. When these unfortunate little ones are seven or eight years of age their legs are swathed in bandages so tight as to stop the circulation. The limbs thus atrophy, but sometimes, when the child is exceptionally strong, only one leg is a "success," the other being merely anchylosed. In this cruel business perverted religion plays a part, the children being made to believe that they are gaining Paradise. The parents receive 5d. a day for one year, or 10d. if their child is blind or has lost an arm besides. In 1887, M. Waldeck Rousseau, when Minister of the Interior, forbade the *culs-de-jatte* to enter the French territory.

Drinking and Crime.—It is a curious fact, and one from which the Prohibitionists will derive little comfort, that while crime has decreased in England, the expenditure for drink has increased by about eight millions of dollars a year.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 25, 1892.

	Cases.	Deaths.
Typhus fever	2	1
Typhoid fever	11	3
Scarlet fever	90	19
Cerebro-spinal meningitis	2	5
Measles	321	25
Diphtheria	65	25
Small-pox	8	2
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

The Association of Medical Officers of the Militia of Canada.—The first annual meeting of this Association was held at the Canadian Military Institute, Toronto, on June 2d and 3d, Dr. F. W. Strange, I. S. C., President, in the chair. The General Secretary, Surgeon G. Sterling Ryerson, read letters of regret from several invited guests who were unable to attend. He also announced that ninety-one surgeons had joined the Association. The draft of the Constitution and By-laws of the Association was read and confirmed. The President then delivered his annual address, which dealt at length with the defects and requirements of the militia medical service. Among other reforms he advocated the establishment of chairs of military medicine and surgery in the universities. Dr. Warren, Second Dragoons, read a paper of great interest on "Ambulance Work during the Franco-Prussian War of 1870–71." Dr. Warren was with the Anglo American ambulance under Drs. MacCormac and Marion Sims, and saw a great deal of service at Sedan and elsewhere. Dr. Daniel Clark, Inspecting Surgeon United States Army during the late war, read a paper on "Some Brain Wounds, with Results." Dr. Clark's paper went to show how large portions of brain-substance may be shot away, or large foreign bodies may lie within the cranium, without causing serious functional disturbance. Dr. McCrimmon, Twentieth Halton Rifles, read a paper on "The Sanitation of Camps of Instruction." A lengthy discussion on the present state of the militia medical service then took place. It was generally admitted that the present system is defective and that various reforms are urgently needed. In the evening a smoking concert was held at Dr. Ryerson's residence, which was attended by nearly all the officers of the Toronto garrison as well as the members of the Association.

Session of June 3d.—The President took the chair at 10.30 A.M. A paper was read by the Secretary, in the absence of the author, on "Some of the Experiences of a Surgeon during the American War," for Dr. William Canniff. Dr. Canniff entered the service of the United States as Acting Assistant Surgeon, in May, 1863, and was ordered to the Army of the Potomac, and arrived on the field just after the bloody battle of Chancellorsville. He did not, however, remain long at the front, but was offered the superintendentship of one of the Lincoln hospitals in Washington, where he saw military surgery on a large scale. At the conclusion of this paper the Association passed into executive session, and elected the following officers: *Hon. President*, Surgeon-General Bergin; *President*, Surgeon F. W. Strange, I. S. C.; *Vice Presidents*, Surgeon Moore, Forty-first Brockville Rifles, of Ontario; Surgeon Roddick, Prince of Wales's Own Rifles, Montreal, of Quebec; Surgeon-Major Connell, Carlton Light Infantry, of New Brunswick; Surgeon MacGillvray, Ninety-fourth Highlanders, of Nova Scotia; Surgeon Jenkins, Garrison Artillery, Charlottetown, of Prince Edward Island; Surgeon G. T. Orton, Ninetieth Winnipeg Rifles, of Manitoba; Surgeon Duncan, Royal Canadian Artillery, of British Columbia; *Treasurer*, Surgeon Tracy, Forty-ninth Regiment; *General Secretary*, Surgeon G. Sterling Ryerson, Royal Grenadiers, of Toronto. It having been resolved to hold a special general meeting in connection with the Canada Medical Association at Ottawa, in September, the Association adjourned.

The Need of National Legislation for the Protection of Human Life.—Dr. A. N. Bell read an interesting paper on the above subject before the Section on State Medicine of the American Medical Association, in Detroit. It had been a favorite maxim with him that progress in measures for the protection of human life consisted primarily in making evident the consequences of their neglect. Accordingly, he gave statistics to show the greatly reduced mortality following the enforcement of certain sanitary measures, particularly by the Health Board in New York, and by quarantine and disinfection of infected ships. On the whole, a reduction of about ten deaths per thousand of the population annually had been made in New York City since the establishment of the first scientific Board of Health there, in 1866. Quarantine at that port had been getting worse and worse, until in 1856 it had reached its climacteric period. While the States and smaller communities had done much good work in stamping out epidemic diseases, yet the need of national legislation was seen in the fact that there was too much independent power on the part of the State and municipal officials, and above all, because merchants and their shipmasters did too much as they pleased regardless of sanitary knowledge. Dr. Bell favored national legislation, but believed that it should be through a Public Health Board, rather than through the appointment of a Medical Secretary of Health, who necessarily must be a politician.

Eczema Infantile.—At the Detroit meeting of the American Medical Association, Dr. B. M. Ricketts, of Cincinnati, read a paper on this subject, which he believed to be of greater interest to this section than any of the cutaneous diseases met with during the first five years of childhood. It is a very common disease, and one for which the general practitioner is frequently consulted. He confined his remarks chiefly to the symptoms and treatment of this disease, which is one of the most aggravating as well as unsightly of all those occurring in childhood. It is usually distributed over the hands and face, with a few exceptions over the entire body, and occasions a most intense itching and discomfort. The most common cause of the disease (in ninety-five per cent. of all cases in the speaker's experience) is an excessive use of soap and water. The whole trouble lies in the fact that the mother is too anxious to keep the child's face clean; hence the too frequent use of soap and water. The vesicular form is the most common. After the disease has manifested itself, the child is irritable, restless, loses weight, and has a depressed appearance in general. It may have diarrhœa or may be constipated, or these conditions may alternate with each other. The skin is reddened, resembling erysipelas, with a laceration here and there. Crusts may extend over the body; the temperature is usually from one-half to one degree above normal; the hair is matted together from a pustule here and there over the affected area. When the hands are involved, it is usually on the fingers and dorsal surface that the disease is most extensive. The treatment the author favored was the following: Water in any form is prohibited; a solution of olive-oil and carbolic acid, in the proportion of one to fifty, is applied several times during the day; the use of tea and coffee and all stimulants is forbidden; also all kinds of food that should not be given to children of this age; the child is allowed all the out-door exercise he wants. One-twentieth grain of calomel is given every two hours. If the child does not improve rapidly in a few days, Dr. Ricketts applies salicylic ointment, ten grains to the ounce. He said that he

did not know what influence the mercury had, but believed that it had a systemic effect, perhaps in changing the reaction of the secretions. The serum exuded from the patches turns litmus-paper red, and he thought that his success was largely due to the alteration of these secretions from acid to neutral.

Hard on the Doctor Either Way.—Smith: "I read so many cases of people being buried alive. Is there no remedy for it?"

Jones: "The only remedy I know is for the Legislature to pass a law compelling doctors to finish their work properly."—*Texas Siftings.*

"Medical science has made such progress," said the doctor, when speaking of his profession, "that it is almost impossible for anybody to be buried alive now." Then he wondered why everybody laughed.—*Boston Courier.*

The Incomes of Medical Men.—Mr. Goschen, Chancellor of the Exchequer, has recently made some statements regarding the regular and handsome incomes of medical men, to which *The Lancet* takes exception. This income, says the journal in question, has to be divided among all these persons, whose education has been costly, who have disproportionate expenses of living, and whose calling is perilous to life, and hard and exacting to a degree not true of any other calling. It is scarcely fair of Mr. Goschen to tickle the e rs of the public with statements so misleading. The poverty of the profession is abundantly testified. The state exacts much from medical men and it gives little. It exacts high education and high conduct. It affords them little or no protection. It gives them no prizes. It should at least refrain from misrepresentation of the very returns they themselves make. The income of a medical man often barely suffices for his current expenses, and it ceases with his uncertain and perilous life. It is a rare exception for him to leave anything that can be called a fortune. The average income of medical men is probably under £300 a year.

Diphtheria is prevented in a measure from spreading, according to Dr. J. Lewis Smith, by keeping a quart of water containing two tablespoonfuls of the following solution simmering on a stove in the sick room:

℞. Acid carbolic,
Ol. eucalypti ..... āā ʒj.
Spt. terebinth ..... ʒviij.

Anæmia should be treated, according to Dr. Allbutt, with sulphate of iron in daily dose, gradually increased from three to twelve grains. Pills of the dried sulphate are best made fresh without gum. One grain being given three times a day, for a week, then two grains for ten days, then three, and possibly four.

Nurses and Religion.—Professor Virchow, in the Berlin Municipal Council and in the course of a debate on the new Municipal Hospitals, has been speaking in his most vigorous style against what he is pleased to call "the intrusion of religious arrogance" into hospital nursing work. "Everybody knows," he says, "that creeds claim supremacy in the healing of the sick; but we are profoundly interested in keeping away this conflict from the sick-bed, and in permitting the spirit of humanity alone to assert itself there. . . . The community establishes numerous hospitals, and thus has an opportunity of providing for the training of sick nurses without regard to creed." It will have to be admitted, however, that the religious spirit was first to respond to the call for attendance on the sick. If hospitals had had to wait for the latter-day training-school, the sick would have suffered badly.

The Congress of Physical Education recently met in Paris, and after a five days' meeting the following resolution was passed: "That every college, school, or teaching institution whatever, primary or secondary, should have an open space where pupils can carry on games and sports. That shooting should be taught, target and shot being furnished by military authorities. Boxing, wrestling, and fencing should be taught in all *lycées* and colleges. Swimming should be compulsory. A model running ground should be laid out, and a sum should be given for buying velocipedes. That children under thirteen should be forbidden to learn bicycling. That pure woollen clothes should be worn in all schools during the exercises. A register of the physical condition of each pupil should be kept after the examinations of physical exercise; his dexterity, chest girth, and the functions." All members except six voted in favor of the principle of extending the powers of the medical councils.

The Difference Between Drunkenness and Inebriety is stated by M. Trelat thus: "Drunkards are people who drink whenever they find an opportunity for drinking; persons affected with inebriety are diseased, and drink only when the attack seizes them." Drunkenness is a vice; inebriety is a disease.—*Ex.*

Eucalyptus Honey, made by bees feeding upon eucalyptus flowers, is the latest remedy advocated for the treatment of pulmonary phthisis. It is said to possess the same antiseptic properties as the medicinal preparations of eucalyptus.

Religion and Measles.—A correspondent of the *D. Med. Zeitung* is responsible for the following curiosity: In the writer's district Romanists and Protestants are in almost equal numbers, and they live scattered among each other. There are two schools. In the Romish schools are one hundred and forty-seven children in two classes, and at seven minutes' distance is the Protestant school, with one hundred and twelve children in one class. In the Romish school one hundred and thirty-nine children were ill of measles, besides a large number of younger children and infants, while among the Protestants not a single child was ill, not even one. The children with all this are in daily contact, using the same wells and playing with each other. The writer declares himself at a loss to account for this singular freak of nature. An old woman of the place thought the Protestants had another "Herrgott."

Chicago Medical Colleges.—Rush Medical College graduated a class of 142 on March 29th. The Chicago College of Physicians and Surgeons graduated 42 on the same date. The Woman's Medical College has graduated a class of 19.

Seven Babies at a Birth is rather a remarkable showing. Marc Juneau, a French demi-mondaine of Guayaquil, Ecuador, is said to have given birth to seven children, all perfect and healthy.

The Mortality of War.—In the past century it is estimated that over nineteen million persons have been killed in the wars of civilized countries, and twelve hundred millions during the last thirty centuries. Flammarion, the astronomer, makes some curious calculations regarding this mortality rate. The blood of the victims would amount to eighteen million cubic metres. This quantity of blood weighs 18,900,000,000 kilogrammes. It is an unfailing stream, which every hour since history began has unceasingly poured 680 litres of blood to dye the royal purple worn by the occupants of imperial thrones. If the 1,200,000,000 skeletons should rise and climb one upon another the ladder thus formed would reach the moon, coil about that body, and, continuing onward, would mount into infinite space four times as far again, that is, 500,700 leagues in height. The corpses, if thrown into the channel at Calais, would form a bridge between France and England and separate the ocean from the North Sea by a weir. If only the heads of the men slaughtered in war were taken and placed side by side, a band would be formed reaching six times around the world.

THE LIMITATIONS FOR VAGINAL HYSTERECTOMY IN MALIGNANT DISEASES OF THE UTERUS.[1]

BY J. E. JANVRIN, M.D.,

GYNECOLOGIST TO THE SKIN AND CANCER HOSPITAL, NEW YORK, ETC.

THE short paper which I have the pleasure of reading before the Fifth District Branch of the New York Medical Association will be of a practical character, and confined simply to those cases of carcinoma or epithelioma of the uterus, including also cases of sarcoma, in which it seems to me that vaginal hysterectomy is demanded.

I shall not attempt to discuss the propriety of this operation as against the high amputation and cauterization as practiced by Dr. Byrne, of Brooklyn, and Dr. Baker, of Boston, in cases in which the cervix is involved, but simply deal with the operation (vaginal hysterectomy) and its limitations under certain conditions and in certain cases. During the past ten years, both in this country and abroad, this operation has gained a strong foothold, and is now accepted, not only as a perfectly justifiable one, but as the operation most desirable in certain cases; and it is my object in this paper to place in a very concise form the class of cases in which it seems to me that the operation ought to be done.

In 1887, Dr. August Martin, of Berlin (from advance sheets of the "Annals of Gynecology"), after going pretty thoroughly over the subject up to that date, concluded his paper as follows: "I recommend the vaginal extirpation of the uterus as the operation, as the means which we ought to apply, in cases of cancerous diseases of the uterus, as long as the disease is limited to the uterus itself."

I believe that the profession in general has accepted this idea, and that most operators, both here and abroad, have, in their selection of cases, confined themselves to this rule; and for that reason have rejected as unfit for extirpation all cases in which there has been ever so slight an invasion of the vagina, and also all cases in which there seemed to be an extension of the malignant disease into the uterine adnexa. Up to three years ago, in determining as to the propriety of this operation, I was always guided by the same rule, and did not knowingly attempt the removal of the uterus in any case in which I had good reason to think that the disease had extended beyond the uterus.

There are many cases, however, in which the cervix or the body, or both, are diseased, in which the uterus is not perfectly movable, not from an extension of the carcinomatous condition to the appendages, but simply as a result of old pelvic peritonitis. In fact my own observations during the past few years have convinced me that the appendages do not become involved in a cancerous infiltration until the general condition of the patient is such that no surgeon, accustomed to operate in this class of cases, would think of performing this operation; *i.e.*, if there is an extension to the appendages, the patient's cachectic condition would be such as to place her beyond any permanent benefit to be derived from the operation. Bearing upon this point of extension of the disease to the surrounding tissues, my observation has taught me that it is much more apt to occur in the *cul de sac* by direct infiltration from the cervix, in cases beginning in the cervix, and then into the pelvic peritoneum, than in the adnexa; and also in some cases it will be found even in the cellular tissue between the bladder and uterus. I have met with three such cases, in two of which the posterior wall of the bladder was involved. In giving an opinion as to the proper limitations for this operation it has struck me that it is best to start with some definite idea as to the usual course pursued by cancerous disease of the cervix and uterus. My own experience, gained principally during the past ten years, has led me to believe that the following table pretty fully covers the usual path pursued:

1. Epithelioma developing upon the cervix.
2. Epithelioma extending up and into the cervical canal.
3. Epithelioma extending up and into the uterine body.
4. Epithelioma extending to the tissues surrounding the cervix.
5. Epithelioma extending downward upon the vaginal mucous membrane.
6. Epithelioma extending downward upon and through the vaginal wall.
7. Epithelioma or carcinoma developing primarily upon the endometrium.
8. Its extension to the body of the uterus.
9. Its extension to the uterine adnexa.

With this table kept clearly in view, I think we can safely and justifiably include in the list of operative cases quite a large percentage over and above those in which the cervix or the cervix and body are involved; and these additional cases will be confined to instances in which the disease has extended simply to the mucous covering of the vagina (Class No. 5), and also those cases, already spoken of, in which there is a certain amount of fixation of the uterus by old pelvic inflammatory deposits, but in which the malignant disease is still confined to the uterus itself.

To come to a proper decision in these border line cases is a matter which, as a rule, can be pretty readily determined, and with perfect justice to the patient.

First. As to cases in which the disease has extended downward *upon* the mucous surface of the vagina. This condition is, I think, generally brought about simply by attrition. The epithelomatous disease of the cervix coming in direct contact with the mucous surface of the upper part of the vagina simply irritates at first, but gradually, as the membrane becomes denuded the poison becomes absorbed by it, and a focus for extension is added to the case. Fortunately, for quite a time, in most cases, the conservative resources of nature are called into play, and a deposit of healthy, newly formed connective-tissue proliferation takes place in the vaginal wall, thus separating it from the glandular and cellular structures beyond. In such cases an examination will show an extension of the disease simply to the mucous surfaces, the vaginal wall slightly, if at all, thickened, and no cancerous infiltration whatever under the wall, the vagina in all respects, excepting as to its mucous membrane, being practically normal. This condition does not in any way counterindicate the operation. It simply complicates it by necessitating the removal of that portion of the wall upon which the disease has started, together with a half inch or more of the healthy tissue below. This is best done by making the circular incision through the vaginal wall at the proper point at the beginning of the operation, dis-

[1] Read at the Eighth Annual Meeting of the Fifth District Branch of the New York State Medical Association, held in Brooklyn, May 24, 1892.

secting upward and ligating any vessels which may cause sufficient bleeding as to require it, and then as you reach the outer border of the cervix go on in the usual manner and extirpate the uterus. I have had two such cases within the past three years—one done about three years since, and the other three months since. There has been no return of the disease in the first case. In the second, of course, the time elapsing since the operation being but three months, it is impossible to foretell the result. All that I can say is this, that the patient is the picture of health at the present time, and I expect a perfect cure in that case also. Several other operators have had a similar experience during the past two years. Drs. Krug and Polk have reported each two cases, I believe.

As to the other class of cases, viz, those in which the disease is located in the body of the uterus, or in the body and cervix, and in which there are also evidences of thickening in the broad ligaments. In such cases there exists a condition in which grave doubts as to the propriety of extirpation may arise. As stated before, if this thickening is due to an extension of the carcinomatous infiltration into the ligaments, tubes, ovaries, and peritoneum, the general condition of the patient is almost always such that the operation would not be thought of, but if the thickening is due to old pelvic inflammatory deposits and there is a history of such inflammation, the condition of the patient will not have been affected to any such extent as to preclude the operation. This condition, however, renders the technique of the operation decidedly more difficult, often absolutely preventing us from drawing the neck of the uterus down to the vulva, and consequently compelling us to perform the most difficult steps entirely by the sense of touch. Where there is a well-grounded doubt as to the character of these deposits in and around the broad ligaments, I have, on several occasions, decided the matter to my own satisfaction to a great extent by the sense of touch; the thickening from simple inflammatory causes always having somewhat of an elastic sensation, while that from cancerous infiltration is always excessively hard and firm. This point in this class of cases, in connection with the patient's general condition, will almost always serve to aid us in making a proper selection for the operation of extirpation.

In many cases of epithelioma of the cervix the tissue is already breaking down and the destructive process has begun to invade the mucous covering of the vagina before the patient seeks relief. In such cases a thorough curetting away of as much of the diseased tissue as is possible with the sharp curette, the application of some cleansing styptic and the subsequent dressing every second day with a ten per cent. dry iodoform gauze, continued for ten days, will be of great benefit in preparing the case for the final operation, extirpation. When in any case of suspected carcinomatous disease of the endometrium or of the body in which the local and rational symptoms are not sufficiently well marked to decide the case absolutely, we should always employ the sharp curette and thoroughly scrape away sufficient tissue to examine microscopically. This will enable us to decide the question of malignancy beyond a doubt in nearly every case.

A few words as to the size of the uterus as applied to the limitations of this operation. I have had occasion to operate in several cases in unmarried women in whom the uterine cavity measured four and a half inches in depth, one a case of sarcoma, another a carcinoma, complicated by a fibroma, as large as a pullet's egg, and situated in the left horn of the uterus. In this latter case it became necessary to make deep incisions into the labia on either side in order to get room enough to extract the uterus, and even then I was oblized to use my "ligature carrier" (devised for cases in which the vagina is small and also for cases in which the uterus from any cause cannot be sufficiently well drawn down to allow the application of the ligatures by the ordinary curved needle), and with this "carrier" there was very little difficulty in throwing the ligatures around the broad ligaments. I believe it is rarely necessary to use clamps; and their use certainly is not as desirable or as surgical as the ligature, and they are, generally, uncomfortably borne by the patient.

To summarize the points presented in this paper I would say: That I most heartily recommend vaginal hysterectomy, not only in cases of cancerous disease of the uterus, as long as the disease is limited to the uterus itself, as recommended by Martin and all other operators, but also in all cases in which the vaginal mucous membrane has been attacked, but in which the subjacent tissues are not involved; and also in all cases in which the thickening in the broad ligaments, tubes, ovaries or peritoneum is presumed, after a most careful examination of the case, to be purely of an inflammatory or plastic character.

VAGINAL HYSTERECTOMY FOR THE RELIEF OF MALIGNANT DISEASE.

By ALEX. J. C. SKENE, M.D.,

BROOKLYN, N. Y.

THE most careful attention that I have been able to give to the subject of the relative merits of vaginal hysterectomy in the management of malignant disease, has led me to the conclusion that it is the most reliable surgical treatment in certain conditions and under certain circumstances. I am firmly convinced that within certain limits it is the best operation at our command, and that when confined within those limits it is undoubtedly the best. I am equally well satisfied that it should only be classed among the other recognized methods of treatment, and should *not* take the place entirely of all others. The operation is indicated, in my opinion, when the disease occurs near to or after the menopause; when it begins in the endometrium, more especially in the body of the uterus; when a positive diagnosis has been made; when the disease has not involved the vagina or the Fallopian tubes to any marked extent, and before necrosis has begun in any part of the abnormal tissue.

The reason for setting these limitations to vaginal hysterectomy may be briefly given as follows: If vaginal hysterectomy is performed before the menopause and the ovaries are not removed, the patient will suffer great constitutional disturbance from an enforced amenorrhœa; on the other hand, if the ovaries are removed before forty-five or thereabout, the menopause which is produced thereby so modifies the general health of the patient as to favor a recurrence of the malignant disease. For these reasons, then, the age of the patient should be taken into account in electing this operation.

In regard to the starting-point of the malignant disease, this has a very important bearing in regard to the choice of the operation. In the rare cases in which the disease begins in the cavity of the body, vaginal hysterectomy, in my opinion, is the only operation that promises the slightest benefit, and should invariably be employed if the age of the patient is favorable. To a certain extent the same holds true when the disease begins in the cervical canal, and there progresses without involving the cervical portion of the vaginal mucous membrane. It is in those cases where the diagnosis is the most difficult to make, and almost always, I fancy, necessitates a curetting in order to determine the nature of the abnormal tissue.

I am satisfied that mistaken diagnoses have interfered with our obtaining reliable facts regarding the real value of hysterectomy. This I presume to infer from the fact that there are a number of cases recorded where hysterectomy has been performed for supposed malignant disease, but the most careful examination of the specimen failed to give any evidence that such was the case. A similar error, though far less grave, I am sure has been made in cases of uterine adenoma, which the microscopists have told me is not so easy to differentiate from ma-

lignant disease; and they further justify the operation by the assertion that adenoma of the uterus, as a rule, is followed by malignant disease in the great majority of cases. In view of these facts regarding those cases where the disease begins in the cavity of the uterus, I insist upon it that the testimony of the pathologists, and the clinical history obtained after a thorough curetting, shall agree before deciding in favor of hysterectomy. Another limiting condition is the limitation of the disease, that is to say, it should not extend beyond the uterus, either in the tissues above the vagina, or into the vaginal wall itself, to an extent which should make it even difficult to separate the uterus and all diseased parts from the surrounding tissues and organs. If the disease has advanced so as to make it difficult or impossible to separate the uterus from the bladder and rectum and ureters, the danger of the operation is, of course, greatly increased, and the danger also of leaving tissue which is affected is also very great.

Finally, I think that, while vaginal hysterectomy is not contra indicated, it is much more likely to be followed by unfavorable results, when necrosis has begun in the diseased tissue. In such cases it is almost, if not entirely, impossible to remove the uterus in the usual way without getting septic infection which may prove fatal.

These are in brief my reasons for insisting upon the conditions and circumstances referred to, before resorting to vaginal hysterectomy. It will be seen from this that, while I strongly advocate vaginal hysterectomy in suitable cases, there remains a large number, perhaps the majority, of malignant diseases of the uterus, in which I prefer other methods of operating, such as those adopted by Sims, Byrnes, and Baker. I do so because in many of those conditions that have been hinted at, I am confident that high amputation, curetting, and cautery are safer, indeed, almost entirely safe, and I believe they are as sure to give as complete and prolonged relief as vaginal hysterectomy.

I might sum up the whole argument in a sentence by saying that in certain cases of cancer of the uterus vaginal hysterectomy is by far the best treatment, and gives more perfect relief and longer life than any other method. In other conditions it is a more dangerous operation by far, and does not prolong life in a greater degree.

It seems to me, entertaining as I do the opinion that vaginal hysterectomy is one of the ways, not the only way, of managing such cases, that it is hardly judicious to compare this operation with others, because where the one is admissible and advisable, the others are not.

These remarks have been made after taking it for granted that vaginal hysterectomy in the treatment of malignant disease is a necessary and advisable operation, and its merits have been discussed in a relative way in regard to other surgical procedures for the relief of malignant disease. Some very important questions relating to this subject yet remain to be discussed, but I am not sure that we have sufficient data to come to any definite conclusions. I refer to the question as to how far surgical means, say hysterectomy, for example, is capable of prolonging life and saving human suffering. We know that the mortality has been very high, and although it has been greatly reduced and rendered a much safer operation, especially in properly selected cases, still the mortality is high. And again, granting that recurrence is less liable to occur as soon as it does after other forms of treatment, a point that is not by any means well proven, the question still remains, has human life been prolonged by this treatment? and if so, to what extent? My own opinion is that the saving of human life has not been so marked as to make one a very great enthusiast in regard to this operation, but I believe that it is considerable; and more than that, the relief from human suffering has been such as to prejudice me in favor of the operation. I base this statement upon what I believe to be a fact, that those who do not recover only lose but a portion of their days, and such days as have not much comfort or usefulness in them; and again, those in whom the disease recurs soon after a complete recovery, the disease usually terminates fatally, with less of that time of extreme suffering. However, we require far more facts, obtained from accurate observers, before we can really estimate the true value of the operation. Perhaps future experience will greatly extend the limits of the operation, but for aught we know yet, it may further circumscribe it.

There is another point which I now have under observation, and have had for some time, and that is the general condition of patients suffering from malignant disease of the uterus. It is becoming evident to me that there is a vast difference in the general condition of patients, some being quite in favor of the operation, others almost forbidding it, even when the local conditions indicate it. I do not mean by this the difference between those in whom the disease seems to be entirely local, where in others the general organization seems to be suffering, but I believe that there are certain organizations, especially those of a chlorotic order, where the circulatory apparatus is imperfect, and where they are prone to degenerations of all kinds—renal, hepatic, and so on—the cases that are always most liable to develop malignant disease, that it is almost useless to employ any surgical treatment; for if they apparently recover, and the operation is as complete as it can be, the disease almost immediately recurs. I, of course, include in this class those in whom the pulmonary artery is undersized, a condition which has been found (post mortem) in all cases observed who died rather early in life from malignant disease in any part of the body. Perhaps those might be said to have the cancerous diathesis in variously marked degrees. Now, it is quite possible that as we acquire more skill in detecting this diathetic condition, we may be able to extend, or contract, the limits of surgical interference in malignant disease of the uterus.

SYPHILITIC HEMIPARAPLEGIA.[1]

By S. T. ARMSTRONG, M.D., PH.D.,

VISITING PHYSICIAN TO THE HARLEM HOSPITAL, NEW YORK, ETC.

More than two score years have passed since Professor Brown Séquard published his discovery that there was a decussation of the conductors of sensitive impressions in the spinal cord, refuting the previously entertained Galenical idea that the contrary was the case.

So it has since been accepted by neurologists that a focal lesion involving only one side of the lower thoracic or the lumbar segment of the spinal cord would cause hemiparaplegia. By this is meant a condition producing on the side of the lesion paralysis of motion, with or without cutaneous hyperæsthesia, lessening of reflex action, impairment of the muscular sense, and elevation of temperature in the lower extremity, while on the opposite side there is a loss of the cutaneous sensation only. As a tribute to the discoverer of the decussation of the sensory fibres in the cord, Dr. Radcliffe proposed that cases of unilateral lesion of the spinal cord be called Brown-Séquard's disease. To this proposition that physiologist dissented, on the ground that a disease is constituted not only by a group of distinct symptoms, but by the existence of the very same kinds of organic alterations in all cases of it; and as a tumor, a hemorrhage, a knife-wound, etc., may produce the organic alteration, this form of paraplegia cannot constitute a special disease. Notwithstanding this protest, Brown-Séquard's paralysis is a more frequent appellation than hemiparaplegia for those cases of unilateral disease of the spinal cord in which there is paralysis of motion of one lower extremity with paralysis of sensation of the other

While the protean character of syphilitic lesions is well known, and the possibility is recognized of almost any nervous disease being caused by syphilis, all authorities

[1] Read before the Fifth District Branch of the New York State Medical Association, May 24, 1892.

agree that lesions of the cord are rarer than those of the brain; and an extensive personal experience with the disease as seen in general hospitals, as well as a reference to the published literature, both of syphilis and nervous diseases, evidences the great rarity of this variety of syphilis of the spinal cord.

Undoubtedly all agree with Leyden, Moxon, and others that the foundation of a diagnosis of syphilis of the spinal cord is based principally upon the antecedent existence of constitutional syphilis, and the absence or insufficiency of all other causes that may produce the existing symptoms. In the following case there is a clear specific history, and the improvement under specific treatment justified the diagnosis of the cause of the lesion.

A. L——, aged forty-one, a native of Norway, a seaman by occupation, first came under observation at the U. S. Marine Hospital, New York, on June 22, 1888. He was suffering with pain in his hips, knees, and feet that had existed for two weeks. Two and a half years before admission he had had a chancre that was followed by a papular eruption, for which he had been insufficiently treated. He was placed on suitable treatment, and on July 11th I operated upon him for a stricture of large calibre. He was discharged from the hospital on July 24th, free from pain, excepting slight tenderness in the heels. He was readmitted to the hospital on January 29, 1889 suffering with pains in his shoulders, arms, back, and chest. He stated that he had suffered more or less from rheumatic pains since his discharge from the hospital, but they had been particularly severe during the week preceding his admission. He had an indurated ulcer on the side of the tongue that had been present for some time. He had had incontinence of urine for two weeks. He was at once placed upon iodide of potash treatment.

On February 4th there was a sudden paralysis of the right lower extremity; the left could be moved easily. The patellar tendon reflex was absent on the right side; and on the left but a moderate reflex was obtained. The cremasteric reflex on the right side was diminished when compared with that on the left. The skin of the soles of the feet was too thick to obtain the plantar reflex. The dynamometer showed a compression force of 35 kilogrammes in the right hand; 30.75 kilogrammes in the left. The æsthesiometer showed normal tactile sensation on the anterior surface of the body until the thighs were reached; on the left thigh sensation was diminished from the inguinal region until in its lower portion, and in the leg there was a complete loss of sensibility.

On the anterior surface of the right thigh and leg there was a very slight diminution of sensibility. Posteriorly the same results were obtained, excepting that anæsthesia commenced at the left nates. There was diminution of the thermal sense in the left extremity. There were incontinence of urine and fæces; examination of the urethra showed that the stricture had not recurred. Occasionally he had a sensation of constriction about the abdomen, below the navel. On sitting up in bed he had pain in the lumbar region, but it was not definitely localized. No temperature variation was noted in the right lower extremity.

It was believed that the persistent pain in the lower extremities for the preceding seven months were indicative of the pathological process that was going on about the cord, and that had culminated in this paralysis. The symptoms indicated a lesion of the cord in the region of the last thoracic or first lumbar vertebræ. Daily increasing doses of iodide of potash were given, but this was later limited to sixty grains a day, with the addition of syrup of the iodide of iron, as he was quite anæmic.

In two weeks the patellar reflex on the right side gave a tardy response, and it seemed to react better each day. The bladder held urine for a longer time, and there was no incontinence of fæces. The patient was given crutches so that he could have the benefit of exercise, and he was able to walk with them for a short time.

February 24th.—He walked alone.

February 27th.—A note was made that the gait in walking was good; but the strength improved so slowly that an experiment was made of suspending the patient for a few minutes in Sayre's apparatus, so as to induce or hasten the absorptive process that was believed to be going on in the affected segment of the cord by stretching as for locomotor ataxy. He thought his extremities were stronger after the suspension, so he was placed in the apparatus daily.

On March 4th an increased frequency of micturition was noted; on the 6th, there was stillicidium; on the 7th, retention of urine; and on the 8th, a chill that could not be attributed to any other cause than some evil effect of the suspension, that was accordingly discontinued. Five days later the vesical symptoms had disappeared.

March 22d.—The dynamometer showed equal compression force in the lower as well as in the upper extremities. The patellar and cremasteric reflexes were normal. The muscles were firm, and the measurements of each limb gave similar circumferences. With the æsthesiometer no difference could be detected in the two extremities. Thermal sensations were normal.

March 24th.—The patient was discharged for outpatient treatment, as he was able to be on his feet all day, and his general condition was very good. He went to sea, was away several months on a trip, and was unable to continue the specific medication. He returned to the hospital with well-marked symptoms of posterior spinal sclerosis; but, as I was transferred from that hospital, I could not follow the course of the case.

To resume, we had a case of a middle-aged man, subjected by his vocation to exposure, who had syphilis of three years' duration, who suddenly presented a hemiparaplegia with the following symptoms:

	Right leg.	Left leg.
Local temperature	Normal.	Normal.
Voluntary movement	Absent.	Present.
Reflex movement	Absent.	Knee-jerk diminished.
Touch sense	Present.	Absent.
Pain sense	Present.	Absent.
Temperature sense	Present.	Absent.
Muscular sense	.....	Present.

Under specific treatment the condition disappeared, but during a suspension of that treatment, symptoms of involvement of the posterior columns of the cord about the same level developed.

The absence of local symptoms over the vertebræ, and the quick recovery following the administration of the iodides, eliminated any disease of the bone as the causative factor. So with any tumor, it would hardly have been absorbed in twenty days. There was no evidence of arterial disease, and yet the sudden onset would suggest hemorrhage or thrombosis, while the recurrence of a spinal trouble suggested syphilitic meningitis with infiltration, as did the earlier persistence of rheumatic pains in the lower limbs.

G. Passovant, in a study of transient paralysis in syphilitics,[1] concluded it was caused by a syphilitic thickening of the arterial coats; and the consequent narrowing of the channel of the vessel impeded the blood-flow, so that in case of diminution in the blood-pressure there was obstruction at the diseased locality, and consequent anæmia. When the heart regained its force, the vessel again dilated, and a restored circulation renewed the activity of the nerve-cells.

Heubner has shown that the specific inflammation may be limited to single spots on the arterial walls, with thickening of the intima, and thrombosis accompanying the endarteritis. Such a condition would explain the sudden onset of the case, and the rapid improvement.

It would in nowise interfere with the possibility of a later specific inflammation of the meninges with infiltra-

[1] Virchow's Archiv, Bd. xxv., 1862, p. 151.

tion extending into the posterior columns of the cord, producing the symptoms of locomotor ataxy.

Folet reported a case of syphilitic hemiparaplegia [1] occurring in a male aged thirty-seven, in whom the paralytic symptoms developed in three days, and who recovered in a year.

Bozire reported a case of the disease [2] in a male aged thirty, in whom the symptoms developed suddenly, and who recovered in a year or more.

Eisenlohr reported [3] a case in a patient aged thirty, who had syphilis eleven years previous to an attack of rectal and vesical paralysis, with paralysis of the right leg, paresis of the left, and greater reduction of cutaneous sensibility in the latter than the former. Improvement followed treatment, but later there was paresis of both legs without ataxia. At the necropsy the dura spinalis was found attached to the posterior portion of the cord by meningeal inflammation from the height of the tenth dorsal nerve to the cauda equina.

The impression seems to exist, though it has been impossible to discover on what evidence, that syphilitic hemiparaplegia is a disease susceptible to treatment. My own case certainly temporarily recovered, though subsequently relapsing, as did Eisenlohr's. The two other cases herein referred to recovered, at least for some time. But the probability of relapse in such cases is very great, especially as either the blood-vessels or the meninges may be affected in other localities and await a suitable time to indicate the existence of the pathological process that is going on.

The necessity of continued specific treatment is apparent; and, as in all cases of syphilis affecting the nervous system, every precaution in therapeutics and hygiene should be observed. In a case in which the history of syphilitic infection is obscure, and yet no other causative factor is discovered, it is much better to assume the specific character of the case than to ignore such a possibility; the latter involves permanent disability if not death, while the former simply involves the administration of the iodides, with occasional inunctions and hot baths.

THE LOST ART OF VENESECTION.

By C. C. P. CLARK, M.D.,

OSWEGO, N. Y.

A FAVORITE lecture of the late Mr. Wendell Phillips was on "The Lost Arts," but he unearthed none that had fallen into more utter oblivion and desuetude than has now, for many years, the practice of venesection. A few years ago the late lamented Dr. Fordyce Barker told how, having occasion to bleed a patient, and, to his surprise, finding no lancet in his own pocket, he sent to all the doctors and drug-stores in the neighborhood without finding one. A like illustrative incident happened to myself a few years ago. Called to a neighboring village in consultation with one of the most eminent among its dozen medical gentlemen, I suggested that our patient should be bled. Our doctor consented, and I sat down to see it done. But after wiggling about a little in an embarrassed way, he called me to one side, and blushingly confessed that, although he had graduated at a New York Medical College, duly walked the hospitals, and been actively engaged in practice for above ten years, yet had he not only never bled a patient, but he had never seen one bled. And not two weeks ago a medical practitioner of like opportunities made to me the same admission. Indeed I don't happen to know of a medical practitioner besides myself who habitually carries a lancet, though doubtless some such there are; and the only kind of case in which I have heard, these many years, of one's being used is that of puerperal convulsions—in which, by the way, its employment is quite superfluous if a couple of grains of morphine are at hand for subcutaneous injection.

Great and numerous as have been the changes in the therapeutic art since this century began, no other among them has been so important as this disuse of bloodletting; for though regular Sangrados were never in any intelligent or civilized community the prevailing type in our profession, as vulgar tradition would have us believe, yet it seems to be quite certain that down to the time when the older among us were born, the lancet was the prime resort and chief reliance in serious attacks of sickness, in grave injuries, and in many cases of mere disordered health. Neither asthenia nor anæmia forbade it to be tried—not but what in some epidemics it was soon seen to be injurious, and given up accordingly.

Moreover, nearly all of the other important changes in therapeutics with which the present century has abounded have consisted in the introduction of novelties, the old instruments of cure—mercury, opium, cinchona, and so on—still maintaining their place. The lancet only has been substantially repudiated, and thus the first became the last.

It is hard to believe that this has been altogether wisely done. The assumption involves that our ancestors were all fools. But no one can read the works of such men as—to confine ourselves to writers in our own language—Sydenham, Cullen, the Hunters, Churchill, Denman, Dewees, etc, without admitting that there were doctors then as earnest, observing, and keen-minded as any of us. When we consider that from the scantiness of medical literature they had little, comparatively, but their own experience to depend on for guidance, it seems to me quite incredible that such minds should, in so practical a matter as the art of therapeutics, indulge, generation after generation, a delusion so monstrous and so injurious as that which is now ascribed to them in regard to venesection. There was great unanimity among them. Cullen's antagonist and brother Scot, John Brown, was the first and only man now remembered who opposed that "antiphlogistic" system of treating disease of which the lancet was the master-tool, and though he did divide the professors of medicine into schools, the adherents of his own school remained in the minority, while the rank and file of the profession, and the people themselves, were nigh all on the other side, and this not alone for attacks of sickness. That

> "A bleeding in the spring
> Is physic for a king,"

was a maxim of almost universal acceptance, and I well remember when it was as common for men and women to come to my father's house, in many instances repeatedly, and ask "to be let blood," as it is now to want to have their lungs "sounded." No doubt the lancet was often heedlessly, and sometimes injuriously, resorted to; but its nigh universal favor among a race of people so practical-minded as our own would seem to be conclusive evidence that its use was often highly advantageous. It has been said in explanation of this altered practice that the "type" of diseases has changed in recent times from what it used to be. But this is a mere assumption, wholly without actual or possible evidence. Granting, as Sydenham contended, that there may be such a thing as a debilitating "epidemic constitution of the air," we have no proof of its increased prevalence in these days. And, as to our own physical systems, it is pretty certain that we are more robust than our ancestors could boast of being.

The principal causes of this remarkable revolution in our treatment of disease are within the personal recollection of some of us. The first serious wound that venesection, in common with nigh all the other chief features of the old practice, received, it got from the vogue of the Thomsonian system. This, though somewhat of a copy, was not an imitation of the Brunonian views, but a genuine autochthon of our own country, so prolific of new

[1] Bull. de Ther., 1867, p. 90. [2] Lancet, 1865, vol. ii., p. 116.
[3] Neurolog. Centralb., 1884, No. 4.

inventions. It repudiated and condemned not only bleeding, but all mineral medicines, purgation, and whatever else might be supposed to reduce the human system. Of the humblest origin, it pervaded the whole land, waging with the old doctrines no unworthy contest, although its greatest prevalence was among the more ignorant populations of the West and South. Its respectable progeny is the eclectic school, with head-quarters at Cincinnati. But the most damaging hurt that our inherited vigorous methods of practice got was delivered by homœopathy. For only from the success of this did we learn—or most of us, at least—that a great majority of sick people will get well without any kind of medicine or other treatment. And naturally the lancet was the first thing to be given up, as by far the most unpleasant of all, both to the bleeder and the bled. Add that there is a natural prejudice against the loss of the vital fluid as weakening, and you have all the arguments that were ever used, or could be, against venesection. Evidence against it—new evidence—there was none. With the disuse our disinclination to its employ has steadily augmented till the estrangement has become settled and almost entire.

Such in brief is the whole story of the decline of venesection to its present low estate from the exalted rank that it had maintained, almost unquestioned, from the time of Dr. Hippocrates to the arrival upon the therapeutic stage of Dr. Thomson. Has it been a good thing? I think not. The question is little arguable from its nature, for it is one of facts, and facts, moreover, that no ingenuity of statistics can ever comprehend or properly array. They are too variable and complex. And yet there are two or three that are worth referring to.

In the first place, the dangerousness and injuriousness of the abstraction of blood are in general greatly overestimated. The late war fully established, in this regard, what we less often observe in civil practice, that a man in health is not only not seriously harmed, but is often benefited, by the loss of blood, even though it be considerable. Thirty years ago it was quite a common thing for men and women in apparent health to ask to be bled. A pint was the regular quantity to be taken. And I never heard any of them complain of damage from it. They said it did them good. It has the effect of fasting. It seems to spur all the functions of organic life to new activity, and from its transient depression vitality mounts quick to a higher plane. As to its effects on sick people, taking the cases by and large, he who reads the "Four Georges," everyone of whom was bled in different complaints more times than he had fingers and toes, will come to the conclusion that it is not easy to kill a man with the lancet, with however little discrimination it may be used. I have myself no doubt that innocent (!) purgation in old times could number its victims by hundreds where venesection, recklessly as it was employed, did by units only. Even in the exhaustion of typhoid fever spontaneous hemorrhage, unless to a fatal amount, has generally seemed to me to have a favorable influence on the case, and the only situations where experience positively warns us against the abstraction of blood is in the well-advanced stages of pneumonia and the exanthems, when vital depression is grave and rapid, and in certain asthenic epidemics. In short, it may be safely claimed that venesection is seldom a dangerous measure.

Meantime, that the diminution of the quantity of blood in an inflamed or congested part has on it in general a highly beneficial influence, is abundantly demonstrated by the effect of epistaxis, of ever so small amount, in a headache, as well as by the great good we constantly see from leeching and cupping—measures fortunately not yet discarded in the profession, though far less often resorted to than they should be; for how few of us have yet learned that a leech applied in season will abort a common whitlow?

Now, if drawing blood from the temporal region is highly useful in inflammatory affections of the eye, as it admittedly is far beyond all other measures put together, why should it not also be of value with an inflamed lung, a congested brain, or an overloaded right ventricle? Reasonable, however, as the affirmative answer to this question may look, it can only be well settled by personal experience. My own has made me attach so great importance to the use of the lancet, that I have got to some extent the name of "the doctor that bleeds." I employ—or perhaps should better say *have* employed—it in nearly all cases of pneumonia, and other extensive inflammations, in violent fevers of whatever sort (Cullen's "synochus"), in congestions of the brain, and in many cardiac affections, and I never in a single instance have had occasion to regret its use.

To show the tolerance of the human system toward this remedy, as well as the benefits of it, I trust it will not be tiresome to your readers if I here set down very briefly two or three instances of my resort to it, and of its effects. It is now more years than I should like to say (lest I be reckoned to be already in my dotage) since I was called to attend upon a lady, in the period of her menopause. She had had a bad cold for some days, which had now become a general inflammation of both lungs, bronchial as well as cellular. A small, quick pulse, severe dyspnœa, scanty expectoration of slightly sanguineous sputa, and some dulness over nearly the whole of the back, with scattered mucous râles, were the chief symptoms. I bled her moderately twice in the course of the first thirty-six hours of my attendance, with some relief. But sent for on the second night, I found her condition so aggravated that I called in a neighboring practitioner of more experience and reputation than I could boast. After examining our patient the venerable gentleman retired to a corner of the room—I shall never forget the scene—and held communion with himself for many minutes. Then he said: "This woman will certainly die if she is not bled, and I guess she will any way. But don't take too much. I will stay by you, and we will see what she can bear."

To make the story short, I bled her four times more within the next two days, to as much as three-quarters of a pint each time, and she got well, having passed through the well-marked several stages of extensive double pneumonia.

In January, 1891, a lady, in her fifty-first year, of whose health I was in charge, and who for some years had suffered under an affection of the heart which I considered to be dilatation of the right ventricle, with repeated dropsical symptoms, was violently attacked with pneumonia. Within thirty hours I bled her three times, to the amount of above three pints in the whole, and with the effect of jugulating the disease—for thirty-six hours later every unpleasant symptom had disappeared—which under any other treatment would certainly have killed her. This was Bouilland's bleeding, *coup sur coup*.

Many years ago I was called to visit a lad still a little under five years of age. He had gone to bed the night before in perfect health, called his mother before she had risen in the morning to give him some bread and butter, but did not make his appearance at the breakfast-table. On going to his room she found him comatose and convulsed. In this state he remained until I saw him, about 2 P.M. the same day. Meantime he had been visited and prescribed for by two other physicians. I found him with a pale and very cool surface, a small, weak, and slowish pulse, deep coma, and continuous clonic convulsion. I told his father that his only chance was in being bled, and when I had with no small difficulty got his consent to a measure that looked so tragical to him, I took from the little fellow's arm sixteen and one-half ounces of blood by weight at a single session. His pulse came up as the blood flowed out in increasing volume, the convulsion abated, his coma seemed to change into a natural slumber. I bound up his arm, and the next morning he was well and at play. Only a few weeks after, I had

identically such a case in a lad seven or eight years older, on whom I used the same treatment, and with the same result. Cerebro-spinal meningitis was prevailing in the neighborhood at that time, a complaint which copious bleeding early, and opium afterward, seem to be the only treatment for.

But if the profession has indeed erred in this so general neglect of the lancet, can we ever return to the right path? Never, certainly, unless hospital doctors and professors of medicine lead the way. Nobody ever wants to be bled, or submits to it, without the strong insistence of his medical attendant in these times. There is a universal repugnance to the measure, both on account of the pain that attends it and our instinctive horror of blood, together with a strong prejudice against it growing out of its disuse. Neither does the young doctor like to undertake it for the first time. It requires more skill to do the little operation well than it does to cut off a leg. And then there is that artery, lying right under where you have to cut. Finally, how is the tyro in medical practice ever to find out when he ought to bleed, unless or until he has had some instruction on the subject from his teachers? Bleeding is the last kind of experiment that he will be disposed to try on his own hook.

But let me tell him this for his encouragement: I have bled many a score of patients, and yet, so far as I can now remember, I never lost a single one after bleeding him, and certainly I have never regretted the operation; while, on the other hand, I feel more sure of having saved some lives by this than by any other means I have ever employed.

February 25, 1892.

THE TREATMENT OF CERTAIN FAMILIAR DISEASES OF THE SKIN.[1]

By R. C. MATHENY, M.D.,

SPRINGFIELD, ILL.

THERE is probably no other class of diseases from the treatment of which the general practitioner so universally shrinks as diseases of the skin. The reason of this, as is so well known, is because of the pertinacity with which they so generally withstand the modes of treatment instituted for their cure. The failure has been mostly due to ignorance, for in fact there is probably no class of diseases that respond more readily to proper treatment than do the common diseases of the skin. In truth, diseases of the skin are among the few afflictions of humanity for which we have what are termed specifics. That long list of acute illnesses, such as typhoid fever, scarlet fever, croupous pneumonia, and the many others with which you are so familiar, have demonstrated their unconquerability, and recognizing this fact, the physician to-day resorts to palliative measures and the prevention of and combating complications.

The successful treatment of diseases of the skin is dependent on information, and this information must cover three subjects: 1, A multiform etiology; 2, a variable pathology; 3, a discerning therapeutics.

For the sake of brevity we may divide diseases of the skin into five classes: 1, Eczema; 2, psoriasis; 3, acne; 4, the neuroses; 5, miscellaneous.

The subjects of the first three classes explain themselves. By the neuroses is meant the numerous kinds of herpes, a considerable proportion of the urticarias, some forms of pruritus, and some forms of alopecia. Under miscellaneous is included all other kinds.

I will speak first of eczema because of its common occurrence, constituting one-third of all diseases of the skin.

To understand eczema, and its treatment, it is necessary to know that it consists of but one process, namely, an inflammatory process, and the various forms of eczema are but the various stages of that process. Bearing this in mind, we know that the treatment of eczema varies with the stage of the disease. Before speaking of the treatment, let me present to you Bulkley's tabulation of the etiology of eczema.

CONSTITUTIONAL AND LOCAL CAUSES OF ECZEMA.

- Constitutional and General Causes.
  - Predisposing.
    - Heredity.
    - Gouty or Arthritic Diathesis.
    - Neurotic Diathesis.
    - Strumous Diathesis.
  - Exciting.
    - Debility.
    - Digestive Disorders.
    - Nervous "
- Local or External Causes.
  - Predisposing.
    - Climatic.
    - Occupation.
      - Sedentary.
      - Standing.
      - Irritating.
    - Diet.
  - Exciting.
    - Climatic.
      - Sudden or Prolonged Exposure.
    - Occupation.
      - Long Confinement.
      - Long Standing.
      - Irritants.
    - Diet.
      - Acids.
      - Sweets.
      - Tobacco.
    - Irritants.
      - Soaps.
      - Ointments.
      - Scalding.
      - Blisters, etc.

Bearing in mind this multiform etiology, you will readily see how important it is to inquire if any of these causes are still active. Treatment, therefore, must perhaps be directed to a change of environment, the alleviation of a diathetic condition, the building up of a debilitated state, and the selection of a proper diet. By the accomplishment of these things probably all cases of eczema would tend to spontaneous recovery. And yet in practice all this does not often come under your control. The case is presented to you when the exciting cause has probably been removed, and the patient asks for relief from his present condition.

The line of treatment resolves itself into two parts: 1. The general and systemic treatment, by which is meant the removal of exciting causes and treatment of any abnormal systemic conditions. 2. The local treatment, specifically directed to the eczematous process.

As to the general treatment, the indications and the manner of fulfilling them will readily suggest themselves to you, bearing in mind that the cause may be a chronic dyspepsia, diabetes, dysmenorrhœa, neurotic dentition in children, etc. The local treatment is governed by the stage of the disease, the treatment of the acute stage being very different from that of the chronic stage. In the acute stage the treatment is palliative, endeavoring to alleviate the inflammation and acute symptoms.

Having removed any known cause of irritation, if inflammation is very acute, it may be necessary to put the patient to bed and remove the clothing. Always avoid the use of water, especially hard water. In the erythematous and oozing stage, as a routine practice, it is probably well always to prescribe an indifferent cooling powder. This may be one of the forms of starch—rice starch being the finest. Of the others we might mention talcum powder, oxide of zinc, oleate of zinc, or bismuth subnitrate. If desirable, this may be flavored. A combination of these might be used, such as:

℞.	Rice powder	40 parts.
	Talcum powder	20 "
	Oleate zinc	10 "
	Bismuth subnit	5 "

This should be dusted freely on the surface, and repeated every two or three hours. Sometimes, on account of the intense pruritus, it is necessary to apply a cooling application. A solution of thymol, 1 to 1,000, is prob-

[1] Read before the Capitol District Medical Society, Decatur, Ill., May 5, 1892.

ably the best. Salicylic acid and menthol are also useful. A mixture such as the following is effective:

R.	Spiritus vini gallici	100 parts.
	Glycerinæ	15 "
	Aquæ coloniensis	15 "
	Tinct. benzoini	5 "
	Acidi salicylici	2 "
	Menthol	1 part.

After applying the above, the powder should be dusted on freely. Continue the cooling treatment as long as the active stage continues, and then use a mild ointment containing substances that influence the inflammation, such as:

R.	Ung. rosæ	20 parts.
	Vaseline	20 "
	Zinci oxidi	15 "
	Bismuth subnit.	5 "
	Ichthyol ammon.	3 "
	Acidi carbolici	1 part.
M.	Sig.: Apply twice a day.	

Nearly all cases of simple eczema will respond satisfactorily to this line of treatment.

In the chronic stage, where you have a thickened hypertrophied epidermis, scaly and hard, the object is to change the chronic to an acute form. For this purpose use a strong ointment to soften the parts and remove the scales. The best thing for this purpose is the unguent. diachylon, with the addition of five to ten per cent. salicylic acid, and continue to apply this until the skin is smooth, when one of the bland ointments should be substituted for an indefinite time.

There is a form of eczema manifesting itself chiefly at those locations where the sebaceous glands are numerous, *e.g.*, on the face, cheeks, chin, and scalp, also on the chest and on the back between the shoulders, characterized by a low grade of inflammation and the appearance of thick, yellow, greasy crusts, and very frequently accompanied by profuse dandruff on the scalp.

It causes the patient to have a very uninviting appearance, and untreated runs an extremely chronic course. And yet there is no form of skin disease which the dermatologist so gladly undertakes to treat as this seborrhoical eczema. It will probably invariably yield to a three to five per cent. ointment of sulphur and resorcin, which may be combined thus:

Ung. rosati	40 parts.
Zinci oxidi	8 "
Lanolini	8 "
Sulph. flor.	2 "
Resorcin	1 part.

There are two diseases that may more or less closely simulate seborrhoical eczema, and which are sometimes mistaken for it, namely, psoriasis and tertiary syphilis in its ulcerative forms.

The importance of a correct diagnosis will at once be appreciated, as the treatment in these conditions is wholly dissimilar. There are certain cardinal points in the differential diagnosis that are almost, if not quite, pathognomonic. Psoriasis constitutes about five per cent. of all skin diseases, and differs from eczema in that it is found more frequently among the affluent classes, and generally in people otherwise healthy.

Psoriasis always begins as minute papules, with a distinct but shallow infiltration, and covered with pearl-like scales. The papules have a red base a little larger than the scales. The scales are easily removed, and show a small bleeding point. The papules grow peripherally, and may partially heal up in the centre and form large diffuse plaques. Always look for the small plaques for diagnosis.

Psoriasis runs a very chronic course, and it is the general consensus of opinion that it is incurable. It causes very few subjective symptoms.

In psoriasis the infiltration is much more superficial than in syphilis, and the redness disappears on pressure; in syphilis the infiltration is much more marked, and the redness does not disappear on pressure. The scales in psoriasis are white and silvery; in syphilis they are gray, and on removal there is not seen the small bleeding point as in psoriasis. In seborrhoical eczema the scales are yellowish and fatty, and are nearly always found on the scalp. Seborrhœa causes the hair to fall out; psoriasis does not. Seborrhœa is generally on the scalp, nose, cheeks, chin, between the shoulders on the back, and on the chest. Psoriasis may appear on any part of the body.

As between the ulcerative forms of syphilis and chronic eczema there may be a close resemblance, and yet these can nearly always be differentiated. Chronic eczema never leaves a scar after healing, while syphilis, because of the depth of the lesion, always leaves a scar. The absence of the scar in a serpiginous inflammatory process is a negative diagnosis as regards syphilis.

Regarding treatment of psoriasis, the lesions can be made to disappear in six to ten weeks, but will probably return in the course of a year or two; one can safely predict a disappearance of the eruption, but not a permanent cure.

The opinion that psoriasis is a parasitic disease is steadily growing in favor, and treatment is being directed accordingly. Local treatment is most important, and the remedies most reliable are chrysarobin in ten per cent. ointment, or ten per cent. solution in traumaticine.

The treatment should not be carried beyond the fifth day, and never after an acute inflammation has been set up. After this a mild ointment should be applied. Pyrogallic acid is one of the best remedies. It can be used in ten per cent. solution, similarly to chrysarobin. It does not cause an inflammation, but colors the skin dark. Application should cease after the discoloration appears, and a mild ointment substituted.

Tar in the form of oil or tincture, or Wilkinson ointment, is good, as is also naphthol β in ten per cent. ointment. Internally, arsenic and potassium iodide in large doses have long been used, and while it may be well to conjoin their administration with external treatment, their usefulness is questioned. Acne vulgaris is one of the most interesting diseases of the skin, because of its common occurrence and of its persistent chronic course. It was not until Unna made clear the etiology and pathology of this disease that its treatment was successfully undertaken. Acne is not a blood disease—to use a popular phrase—and internal medication will generally altogether fail in its purpose. Acne is a local disease, and should be treated locally. It is an inflammatory process affecting the sebaceous glands of the skin. The process may be divided into two parts: 1, Closure of the sebaceous follicle and formation of comedo; 2, suppuration.

The acne is due to a solidification of the secretion within the sebaceous glands, produced by various causes. The amount of fatty sebaceous matter is gradually increased, the gland duct is filled up, and with the undue pressure upon the neighboring parts, together with the previous entrance of the staphylococcus aureus et albus, the acne pustule is produced. If left undisturbed, extensive infiltration beneath the cutis is developed, forming hard nodular masses and the occasional formation of extensive abscesses.

Understanding the cause and process of the acne pustule, the treatment is simple and readily suggests itself. The indications are to dissolve out the plugs of hardened sebaceous matter and the extermination of the staphylococcus, and the prevention of its further development. The hardened sebaceous matter can be dissolved by the occasional washing with an eighty per cent. alcoholic solution, to which as a germicide we may add two to five per cent. of resorcin. At night a ten per cent. sulphur ointment should be thoroughly rubbed in. By this method the occluded glands are relieved, and the causes of suppuration are removed.

When, however, after a long continuance of the pro-

cess the outlet of the glands becomes obliterated by inflammatory tissues, and suppuration is not brought about, there remains in the occluded duct small masses of caseous sebaceous matter. These are not absorbed, but remain encysted in the tissues of the skin for an indefinite time. Internal or external medication is useless in these cases. The treatment is surgical. With a fine-pointed bistoury (I use a cataract knife) make a puncture deep enough to reach the encysted matter, and then apply sufficient force to express it. Then, by treating the wound antiseptically, the incision kindly heals.

On general principles it is probably well also to encourage the various secretive organs, that a tendency to recovery may not be balked by faulty elimination.

The treatment of the neuroses will be taken up at a future time.

A STUDY OF NEUROTIC ECZEMA IN ADULTS.

By CUTHBERT R. BARHAM, M.D.,

PITTSBURG, PA.

Although authorities in a general way refer to nervous causes in eczema, no specific variety attributed to this factor has as yet been isolated.

That neurotic eczema is in itself a variety is evidenced by its location upon the extensor surfaces, by the arrangement of its lesions, and by the course of the disease, its condition varying under circumstances which are certainly not local. The discussion of a few typical cases may lead to a better appreciation of the subject presented.

Case I.—Hannah H——, domestic, aged fifty-five; patient passed the climacteric five years ago, and among other disorders connected with this period had an eruption on the face, similar, as she states, to that now evident. It disappeared after about four weeks' duration. From that time until eighteen months ago she was free from eruption of any kind. Two years ago she went to Ireland, and during the passage was often exposed to changes of temperature. She was subjected to mental worry on account of death in the family and other troubles. She contracted malaria there, and was sick most of the time. Soon after her return, about eighteen months ago, the present eruption appeared. In addition to this, she has had frequent attacks of malaria, during which she is nervous, sleepless, and unusually constipated. The eruption is notably worse after these attacks.

The general condition of the patient at present is good, but she is exceedingly nervous. The urine showed on examination only a slight excess of urates.

At her first examination the condition presented was as follows: The eruption is limited to the lower two-thirds of the forearms and legs, and to the dorsal surfaces of the hands and feet. On the dorsum of the hands, in the interdigital spaces and backs of the fingers, encircling the wrist-joint and the forearms as far as the upper third, are a number of small patches of various sizes and of various shapes, but in the main circular; these patches are in part squamous and in part weeping, showing here and there a patch composed of a group of unbroken vesicles, and occasionally a larger patch in which all three features are shown. The skin of the whole affected surface, but more especially the distinct patches, is thickened and somewhat infiltrated. Unlike eczema, as usually observed, the separate patches are sharply defined. The patch is formed of closely aggregated groups of vesicles in the various stages of papules, broken vesicles with watery fluid exuding, or a raw surface covered with squamæ. But whatever the nature of the patch, its periphery is found to be composed of closely set papules or vesicles, and the division between the diseased area and the healthy skin is sharp and absolute. In short, the separate lesions may be described as patches composed of closely aggregated papules or vesicles, or both. In places the edges of the patches have coalesced, forming large areas of diseased skin, with here and there an island of healthy tissue.

It is perhaps well to state that the term "healthy" is here used in a limited sense, implying that the slight redness and infiltration is not an eczematous inflammation, but due solely to the proximity of the active inflammation in the patches.

On the back of the hands and upper part of the forearm are a number of patches which have appeared recently, and hence merit attention, by reason of their being typical or characteristic lesions in the variety of eczema which we are now studying. They are circular in shape, varying in size from one quarter to one inch in diameter, with sharply defined edges, and are composed of vesicles or papules, in some cases of both, closely aggregated. There is in these lesions no scaling nor weeping, the vesicles not being ruptured. Owing to the recent appearance of the inflammation in this locality, the tissue intervening between the patches is normal, no redness being observed. The skin presents here and there, at rare intervals between the patches, isolated papules or small groups of three to ten papules each. On the older patches, where the disease has persisted for some time, we find crusts identical in every particular with those found in eczema due to other causes. These crusts when removed expose a copiously weeping surface, with here and there a bleeding point. In other words, the process is entirely similar to that observed in ordinary eczema, the difference in the physical signs being due to the peculiar arrangement of the lesions and to the location.

Now, as to the location, while the disease in this instance affects both extensor and flexor surfaces, yet at a glance it is noticeable that a special predilection seems to exist for the extensor surfaces, the lesions being small and widely separated on the flexor surfaces. This, as we all know, is directly contrary to the usual course. The lesions are located on symmetrical portions of the body.

The eruption on the legs presents the same appearance and general characteristics as on the arms, and hence no detailed description is necessary.

The descriptions of the lesions and points in history bearing on the disease have been given in this case with more minuteness and at greater length than may seem necessary to some, but it is because the case presents many points that are important, both in the previous history and in the physical signs; and also because the lesions were characteristic in appearance, the patient having had no treatment for the present attack before coming under my observation.

The treatment was mainly directed toward strengthening the nervous system and reducing the congestion of the diseased areas. The local treatment was directed toward correcting, as far as possible, the conditions present in the diseased areas. We will enumerate here a few of the remedies employed, and the mode of prescribing them. The reasons for their use will be explained later on.

℞ Fl. ext. ergot ..... ʒ iv.
Fl. ext. viola tricolor (pansy) ..... ℥ jss.
Aqua ..... ad ℥ iij.
M. Sig.: ℥ j. t.i.d.

℞ Magnesii carbonatis,
Pulvis zinci oxidi .....āā ʒ j.
Ichthyol ..... gr. xl.
Aqua .....ad ℥ iv.
M. Sig.: Apply to diseased surface three or four times a day.

It is needless to state that the normal functions must be regulated, and of these the most important is a regular daily movement of the bowels. For this purpose I prefer cascara sagrada. It has no lasting or ill effects on the intestines, and may be continued for a long time without leaving the patient constipated. Such was the line of treatment followed. The patient improved rapidly. Later a tonic of iron, strychnine, and quinine was ordered.

and continued for some time after the disappearance of the eruption, which was in about four weeks from time of beginning treatment. The case was kept under observation for four weeks after this, and showed no evidence of return.

Case II.—Gilbert P——, weaver, aged thirty-five. On careful questioning of patient, I could find no evidence of functional disturbance other than obstinate constipation. His occupation was sedentary and he suffered from nervousness, probably due to lack of exercise. He had been troubled with an eruption for two years. It first appeared on the backs of the little fingers, later spreading to the interdigital spaces and backs of the other fingers. At the time of consultation, the skin between the fingers was sodden from exudation. The skin here was too thick for vesicles to form, and the epidermis came off or was raised as a whole in consequence, and as the separate patches had coalesced, it appeared to be one large patch, at the border of which the distinct sharp division from healthy tissue was easily perceptible. On the back of each wrist was a large circumscribed and sharply defined patch. The patches were in all cases moist and very much inflamed, the edges being composed of vesicles. Within the limits of the patch the skin was thickened. The pruritus was excessive. The line of treatment was somewhat different from that in Case I., the conditions not being the same. The aim here was, first, to correct the sodden condition of the tissues. This was effected by means of an ointment :

℞. Magnesii carbonatis,
Acidi borici.....āā ʒ j.
Ungt. zinci oxidi ..... ʒ j.
M. Sig. : Apply morning and night on a piece of lint.

The bowels were meantime regulated by fl. ext. cascara sagrada. Under this treatment the improvement was marked for a time, and at the end of the second week the following was ordered to reduce congestion and as a general tonic.

℞. Tinct. ferri pomati,
Fl. extr. ergot.....āā ʒ iv.
Tr. nucis vomicæ..... ʒ ij.
Aquæ.....ad ʒ iij.
M. Sig. : ʒ j. t.i.d.

More exercise was recommended. A cure was effected in about six weeks, and one month's further observation showed no return.

Case III.—J. M——, longshoreman, aged thirty. In this case, as in the previous one, there was no distinct history of functional disturbance. The man's occupation subjected him to a good deal of exposure, and he stated that he was very irregular in sleeping and eating. The eruption has been present at various times since childhood. It has appeared once on the hands, and once on the ankles, but in each attack the lesions were symmetrical. The lesions present at the first consultation were on the backs of the hands, and consisted of circumscribed patches formed of papules and vesicles, some irritated and weeping, others crusted. The patches were at this time absolutely symmetrical. The itching was excessive. The patient was nervous. The following was ordered :

℞. Ichthyol..... gr. 20
Ungt. zinci oxidi ..... ʒ j.
M. Sig. : Apply twice a day.

For a few days improvement was noted, when the patient left the hospital. He returned in two months' time with elevated, inflamed, and weeping patches symmetrically situated on the backs of the hands and along the ulnar border of the wrists. The strength of the ointment was increased to thirty grains, or six per cent. The improvement was rapid, and patient was discharged with no trace of eruption remaining.

Two months later he returned, with patches of all sizes and shapes and more or less inflamed. All the lesions were more or less infiltrated. The periphery of each patch consisted of a narrow line of vesicles. In some places subjected to motion, as over the wrist-joints, fissuring was observed. The following was ordered :

℞. Plumbi carbonatis..... gr. 80
Resorcin..... gr. 60
Ungt. diachyli..... ʒ iv.
M. Sig. : Apply twice daily.

In two weeks all trace of eruption was removed, and the patient was discharged. He returned in about ten weeks with a fresh, but light, outbreak. The treatment was the same as at last consultation, and the result was prompt.

This case is interesting as illustrating the tendency of the eruption to continual relapses, exasperating alike to patient and physician, showing also the symmetrical arrangement of the lesions, and the futility, so far as permanent cure is concerned, of local medication only ; for it will be noted that in this case no internal treatment was employed.

Case IV.—E. M——, servant, aged forty-three. Constipation was the only functional disturbance ascertained. The nervousness of the patient's manner and speech was noticeable. The eruption appeared on the hands nine months before the patient came under observation. The general characteristics at this time were groups of papules or vesicles of various sizes, forming patches, circular in the main, with sharply defined edges, moist in character, and located on the extensor surfaces of the hands and wrists. It had appeared on the extensor surfaces of the legs during the last few days. Treatment was as follows :

℞. Magnesii carbonatis,
Pulv. zinci oxidi .....āā ʒ j.
Ichthyol..... gr. 40
Aquæ.....ad ʒ iv.
M. Sig. : Apply several times a day.

℞. Fl. ext. cascara sag..... ʒ iv.
Tr. nucis vomicæ..... ʒ ij.
Aquæ ..... ad ʒ iij.
M. Sig. : ʒ j. t. i. d.

Under this treatment there was improvement, but it was slow, and at the end of two months we added fl. ext. ergot to the internal treatment. The dose being ten drops three times a day. The improvement was then more rapid and the patient was discharged cured at the end of four months. By request he reported occasionally to the clinic during the next six months, no return being noted.

Case V.—W. R——, surveyor, aged twenty-four. History was as follows: Suffers from obstinate constipation and indigestion, the stomach being exceedingly irritable. In his profession, when out on duty he is compelled to take his food cold. At such time he suffers very much from indigestion and nervousness, and the eruption is more irritated than usual. The duration of this attack is one year, during which time he has never been entirely free from it. The patient is exceedingly nervous and restless. The lesions presented are circumscribed patches on the cheeks, forehead, and extensor surfaces of the forearms ; they are well marked in outline and present the characteristics enumerated above.

The treatment was directed with the view to correct the indigestion and constipation, and to strengthen the action of the nervous system.

℞. Tr. nucis vomicæ..... ʒ ij.
Acidi phosphorici dil ..... ʒ iv.
Tr. gentianæ.....q. s. ad ʒ iij.
M. Sig.: ʒ j. t.i.d.

℞. Acidi salicylici..... gr. xv.
Ungt. zinci oxidi..... ʒ j.
M. Sig. : Apply morning and night.

The bowels were regulated with comp. cathartic pills as needed. Within the first week improvement was noted, and extract of ergot was then ordered in doses of ten drops t.i.d. to check the congestion of the skin. The favorable course of the disease was checked, after he had

been under treatment three weeks, by an attack of influenza from which it required a week or two to rally. The improvement then continued, and the patient has been for some time almost free from the eruption, but the least indiscretion or dissipation will cause relapse. He is still under observation.

Case VI.—Mrs. B. F——, aged thirty-eight. Eruption has been present for ten years. Prolonged constipation and a generally listless, overworked feeling were the only points ascertained in the history. The patient was pale, anæmic, and nervous. Each cheek presented a large circumscribed patch, one and a half inch in diameter, composed of thickly-set papules. The patches presented scaling, and there was considerable thickening of the skin over the area of the patch. On the forehead were numerous small patches presenting the same general characteristics, though, being of later formation, the thickening of the skin was not evident. No scaling was present.

The history is but a repetition of the others. Internal treatment to regulate the natural functions and the nervous system, and local treatment, according to the conditions presented, would cause improvement, but the slightest indiscretion would cause relapse. Thus relapse followed relapse with tantalizing regularity, in spite of the watchfulness of physician and patient. She is still under observation, receiving treatment when necessary.

The case is mentioned because of the location of its lesions, the significance of which will be shown later in the discussion.

Case VII.—G. W. B——, inmate of a charitable institution, aged sixty-three. Patient presents following history: He was, until five years ago, a prosperous broker, and at this time lost all that he had in speculation. He has no family living, and until lately has lived on the charity of friends. His health is wrecked, and he presents symptoms of disseminated sclerosis of the cord. Constipation is present in aggravated form. The heart is regular but weak. No signs of previous syphilis or arterial sclerosis. Great mental worry and some privation preceded the outbreak of the eruption. The eruption first appeared on the shoulders over the deltoid region, and when first seen covered the extensor surfaces of the arms and forearms, the front of the thighs and knees, and the circumference of the legs, being more developed on the front than on the back of the latter. There was considerable infiltration and scaling over all the lesions. Treatment was as follows:

℞ Fl. ext. viola tricolor (pansy) ..... ʒ iv.
Tr. nucis vomicæ ..... ʒ ij.
Fl. ext. ergot ..... ʒ iv.
Aqua ..... ad ʒ iij.
M. Sig.: ʒ j. t.i.d.

℞ Ungt. picis et zinci ..... ʒ iv.
Sig.: Apply twice daily.

The result was good, and for two weeks the patient improved rapidly, when we attempted to apply an ointment as follows:

℞ Fl. ext. ergot ..... ʒ iv
Ichthyol ..... gr. 40.
Ungt. zinci oxidi ..... ʒ iv.
M. Sig.: External use two or three times a day.

This treatment did not allay itching on the shoulders and arms sufficiently, and the patient kept the parts irritated by scratching. It acted well on the legs. It was discontinued on the arms and forearms and the first ointment was reapplied. Under this treatment the patient was cured in one month, and then entered a home for the aged. Since that time he has had two attacks, and each time it has required about four weeks to get him into shape.

Case VIII.—H. N——, schoolboy, aged thirteen. Eruption has been present since early childhood. After a careful questioning and examination nothing wrong could be detected in the normal functions. He suffers from asthma quite a good deal when near the sea-shore. At such times the eruption is much worse. The patient was a native of Brooklyn, and when away from home suffered very little from asthma, but would be taken with fresh attacks whenever he returned. He was well nourished and large for his age. The lesions were on the extensor surfaces of the forearms and arms, in front of the thighs, on the backs of the legs, and on each cheek. They were more or less circular, sharply defined and weeping, scaling, or simply papular, according to the various stages of the duration. Treatment:

℞ Fl. ext. viola tricolor (pansy) ..... ʒ iv.
Tr. nucis vomicæ ..... ʒ ij.
Fl. ext. ergot ..... ʒ iv.
Aqua ..... ad ʒ iij.

The doses here were rather large, but caused no inconvenience. The local treatment was:

℞ Ichthyol ..... gr. 40.
Fl. ext. ergot ..... ʒ iv.
Ungt. zinci oxidi ..... ʒ jv.
M. Sig.: Apply to lesions twice a day.

The improvement was rapid until the patient desired to go home, when he relapsed. This relapse continued to occur at every visit home, until finally permission to return was refused. The asthma was also treated with indifferent success.

The case was finally cured of the eruption, but not until four relapses had occurred. The case will relapse on the slightest indiscretion.

The object of this paper is to ascertain, if possible, by a careful study and analysis of each case, the etiology of this form of eruption, and to consider its management. As a fitting introduction to the study it will probably be necessary to consider the various disorders that we have seen in the foregoing histories to precede or accompany this eruption, and to study their bearing and influence in its production. Among these disorders, functional and nervous, the most common, and presumably the one having the most bearing on the disease under discussion, is a general weakness of the nervous system. This was noted in the history of every case except the last, and in this instance the patient suffered from a disease generally acknowledged to be nervous in its origin. We have seen that the eruption was preceded by longer or shorter periods of business cares or mental suffering. It is immaterial whether this mental suffering was occasioned by prolonged sickness, trouble or anxiety, or privation; the result is the same, and this result, I think, is in every case that condition of general weakness of the nervous system known as neurasthenia, in which the functions of the nerves are either weakened, or the nice balance of power between the initiatory and the inhibitory centres is destroyed. Thus, either the normal processes of life are too violently, or too feebly, performed, or the action is irregular. From this follow functional irregularities seen in many of our subjects, and the flushings of the skin often confined to particular areas (Strumpel). Occasionally we see more or less permanent vasomotor paralysis, and this would naturally occur in those parts most exposed to influences producing an erythematous condition of the skin, or in those areas unusually well supplied with capillary vessels. Understanding, as we do, so little in regard to the functions of the trophic nerves and the exact mechanism of their action, our discussion of them must necessarily be brief and, I fear, unsatisfactory. At any rate, physiologists tell us that there are certain nerves which affect or govern the nutrition of the parts to which they are distributed. It has not yet been definitely settled whether they run as fibres of the sensory nerves or with the sympathetic system, but it is probable that their greatest influence on nutrition is connected with the power they have of affecting the blood-supply of a part, and secondarily, by their *attributed* power of regulating the absorption by the tissues of the nutrition brought by the blood. The influence of the

nervous system then, in producing, or conducing to, the eruption of eczema, is probably confined to its action on the vaso-motor system and nutrition.

At a later stage we will endeavor to show how and why this eruption thus results.

The remaining irregularities may be summed up under the head of functional disorders. Although important, they are too well known and their results too well understood to require more than a superficial discussion. The most common among these is constipation, often obstinate and of long standing. It may be due to many causes, among which may be mentioned duodenal indigestion, and in every case there is absorption of poisonous substances from the retained fæces. The effect of this absorption is first seen in the apathetic manner of the patient; later he complains of a continual dull headache (Strumpel) Another functional disorder is indigestion, duodenal and stomachic, the latter less often than the former unless it be chronic; for the sympathetic nerves are so intimately connected with the stomach that any irritation in this quarter will cause immediate flushing of the face (rosacea), or localized infiltration from dilated blood-vessels over the body (urticaria). These phenomena are purely reflex through the medium of the sympathetic nervous system acting on the vaso-motor nerves.

Disorder of the reproductive organs is more common than generally supposed; the action here is also reflex (Strumpel). Sickness involving great strain on the nervous system, as the grippe, acts through the nervous system as mentioned in the opening of the discussion. Exposure to extremes of temperature may act in either or both of two ways: 1, By lessening the resisting power of the tissues; and 2, if long continued, by producing a chronic condition of more or less hyperæmia from partial paralysis of the blood-vessels.

It is probable that all of these conditions, except the two last enumerated, act in one way, by lessening the inhibitory power of the higher nervous centres, and destroying that balance of power necessary to a proper action of the trophic nerves and vaso motor system. In one case we see illustrated the connection between the eruption and such purely nervous troubles as asthma. The nervous trouble here is easily explained, if we agree with those authorities who hold that asthma is due to a sudden hyperæmia or urticarial swelling of the mucous membrane of the bronchi. If, on the other hand, we agree that it is due to a spasmodic contraction of the bronchi, the explanation is not plain. This connection established between asthma and neurotic eczema points toward a disturbance of the sympathetic nervous system as a probable cause, or at least a determining factor, of the latter.

Now, for a thorough discussion of the etiology it will be necessary to study the local surroundings and ascertain whether the eruption is dependent on them for its appearance; next, to show the evidence of internal influence in its production. In the first few moments of study of external influences we are convinced that these, if not the primary cause, are at least a potent factor in determining the location of the eruption. In a measure this is true. I have purposely enumerated in the histories the various external influences surrounding the individual cases, and though at the first glance they seem to be of importance, yet on a closer investigation, taking into consideration the location of the lesions, their sharply defined area, and the absolute symmetry of localization, we see that such cannot be the case, *i.e.*, that the eruption is not local in its origin. Let us study the cases in detail.

In the first case there is absolutely no history of local irritation, with the exception of exposure to cold eighteen months previous to the present outbreak. The fact of the examination of urine showing urates, and the fact that the patient had previously had rheumatism, might possibly point to the inference that the eruption was due to retained products that should have been excreted by the kidneys, such as uric acid, etc. But here we note that the lesions are not those seen in the so-called rheumatic eczemas. Then, too, the history of nervous trouble, of attacks of nervousness and constipation being followed by exacerbation of the eruption, and the result of the treatment, all point to the conclusion that it was due to reflex nervous influence.

In the second case, again, we find no evidence of local action, only the nervous history.

The third case presented no history of any kind. The diagnosis being sustained only by the appearance of the lesions and the constant recurrence of the eruption, which, if it were due to local conditions would disappear with the removal of the irritating conditions.

In the fourth case the history is imperfect again, only the course of the disease and the appearance of the lesions guiding the diagnosis.

Case V. presents the most distinct neurotic history of any in the list. The location is not only typical of its nature as reflex, being that of rosacea and the so-called infantile eczemas, but the history shows that the respective exacerbations are dependent only on disarrangements of digestion, and are accompanied by periods of excessive nervousness. There is absolutely no history of irritation other than reflex at any time.

Case VI. is similar, but this history is not so conclusive.

In Case VII. we again have a typical history and a typical eruption; long period of mental worry and unmistakable signs of disease of spinal cord. The lesions were confined exclusively to the extensor surfaces, and differed materially in appearance from those of senile eczema, with which here it might otherwise be confounded, if the patient's age were alone considered. Again, in the eighth case we have the history of disease commencing in infancy as reflex eczema, and persisting under improper treatment, and the accompanying complication of asthma, with each attack of which the eruption becomes more irritated.

Although in the cases cited, as in others studied in this connection, the history of a preceding local irritating condition is most conspicuous by its absence, it cannot be altogether eliminated. We are all surrounded by conditions more or less injurious, and the cases under consideration are no exception. If we admit these to have been present it will not alter the conclusions, for it is hard to admit their direct influence. Bearing in mind the appearance and peculiarities of location of the lesions described in the histories, it is hard to conceive that external influences, so varied as those to which eczema is ascribed, will act through a series of cases affecting symmetrical parts of the body, and showing a tendency to attack the least tender parts of the skin rather than the other. To admit this we must admit a peculiar liability of the surfaces thus affected by preference, and admitting this we admit an internal influence dependent on the nervous system. Except in rare instances I have seen no case in which I could see evidence that the location was influenced by a previous condition of irritation. This irritation was in almost every case due to malnutrition, dependent on varicose veins, and the eruption appearing on such surfaces was not, in appearance, characteristic of neurotic eczema, but seemed rather to be an irritative eczema accompanying the latter. The same will be found true whenever an eruption can be shown to be due in part to external influences. It is on this ground that I contend that neurotic eczema is due to nervous influence alone.

In regard to the theory of direct action on the skin of retained products of excretion, such as uric acid, etc., I think the evidence is against it. It is true that we have eczema in rheumatic and gouty subjects, due probably to this cause, but the appearance and course of the eruption is different from that under discussion. In fact the eruption in such cases does not materially differ from ordinary eczema. The effect of products absorbed from

the bowels during constipation is not yet fully explained, but it is probable that these are toxic alkaloids which act principally on the nervous system. Certainly the lassitude and pain in the head in subjects so affected point to this conclusion. That they affect the skin in some way, reflex or direct, is well recognized. The reader is referred for a consideration of this point to an article in *The Lancet*, December 5 and 12, 1891, on the subject of "Duodenal Indigestion," by Dr. Allchin. Having excluded influences not internal, and indicated a possibility of diagnosis between eruptions due to direct action of retained products of excretion and those due to action through the nervous system, called reflex, we will proceed to discuss the bearing of the nervous system on the disease.

In the nervous system there are but two varieties of fibres that need to be discussed in this connection; these are the trophic and vaso-motor nerves. In regard to the former I am sceptical as to their influence. If the trophic nerves are connected with the vaso-motor system and act by influencing the blood-supply to a part, then undoubtedly their influence is great, otherwise the connection is not plain. The sensory nerves play also, I think, but a subsidiary part in the etiology of the eruption, the intense itching and discomfort being due either to over-stimulation by increased flow of blood, or to pressure by exuded plastic material. The most important part is played, it seems, by the sympathetic or vaso-motor system, and the stimulation is reflex. The inhibitory centres being excited or irritated, and losing control over the "balance of power" at certain points, dilatation of the blood-vessels with exudation of plastic material occurs, forming papules, vesicles, etc.

That a vaso-moter disturbance is, in a great measure, responsible for the eruption, is, I believe, supported by the following features in the clinical history of the eruption: 1. The symmetrical location of the lesions. 2. The sharply defined margin of the affected area, which, in connection with the above feature, points to a nerve influence in its distribution. 3. The location of its lesions on the extensor surfaces of the extremities and on the face, this being the location chosen by erythema multiforme, rosacea, etc., which are admittedly of reflex nervous origin. 4. In a few cases the distribution can be shown to be confined to surfaces supplied by certain groups of nerves, as in Case VII., where the distribution was sharply limited.

It is well known that from the close relation existing between the vaso-motor system and the nerve-supply of the digestive canal prolonged irritation of the latter, as from chronic indigestion or constipation, will cause a reflex hyperæmia of the skin at certain points, notably the face, and sometimes on the extremities. The fact is well shown in rosacea, in which a full meal or irritating injesta will cause flushing over the affected area. Again, the reflex action of the vaso-motor system in producing circumscribed lesions in the skin is shown in the wheals of urticaria. Exudation seen here occurs through some ill-understood action of the nerves on the walls of the blood-vessels, the sensory nerves being secondarily affected by pressure. The exuded material not being plastic, reabsorption easily occurs. In certain diseases of the reproductive organs of women the same phenomena are sometimes observed.

There may be some curious enough to inquire why every person who is constipated or nervous or worn by anxiety is not then afflicted with eczema of this character. To this I can only answer that the skin must be in a condition to be excited to this inflammation, or the nervous system too weakened to resist the impulses due to disordered action. The first may result from a natural tendency of the skin to catarrhal inflammation, which condition is found in some people. The second may be due to decreased vitality of the nervous system from prolonged strain, which in itself, by reducing the general vitality and resisting power of the system, naturally lessens that of the skin, and paves the way for inflammation.

Now, since these influences, be they what they may, act on the whole nervous system with equal strength, it is natural that the weaker parts shall be the first to give way. This accounts for the sharply defined areas of eruption, and for only certain areas being attacked.

It is natural to suppose that if the conditions giving rise to the eruption are not in some way counteracted, other nerves will be affected and other areas involved. This is precisely what happens. With no treatment, new areas are constantly involved, and the cause of the eruption is also indicated in the manner of its spread, for the diseased areas never spread by the edge advancing, which would indicate direct action of the cause on the skin and spread of its area of action, but by the formation always of new patches similar in appearance to the old. This points to the theory that separate and distinct nerve-trunks are successively involved.

The symmetry of the lesions, as to location, points to the theory that there is a connection between the nerves supplying the symmetrical areas, and this fact leads me to select the sympathetic system as the most probable area of the trouble, since the sympathetic ganglia connect with those of the opposite side, across the vertebral column, and it is therefore probable that irritation of one will produce irritation of its fellow.

Having determined that the sympathetic system is at fault, we limit the field of research, and, for the reasons mentioned above, select its especial subdivision known as the vaso motor system as the primary cause of the eruption. It may not be amiss to give again a short *résumé* of the physical signs and clinical course before discussing the diagnosis. 1. The location of the lesions is in every case symmetrical. 2. The eruption tends to attack localities not as a rule liable to eczema, at least in its earlier stages, *i.e.*, the extensor surfaces of the extremities. 3. The arrangement of the lesions differs markedly from that usually observed in eczema. The lesions are not scattered indiscriminately over the affected surface, but are grouped in patches which are more or less circular. These patches are formed of closely aggregated papules and vesicles. The sharply defined edges are made up of a line of papules or vesicles. The periphery of the diseased patch remains distinct, sharply defined, and absolute at all stages. 4. The spread of the eruption is never by a gradual extension of the area of the separate patches, but by the formation of new lesions, in every respect retaining the characteristics of the older ones. 5. The dissolution of a patch is accomplished, not by a gradual shrinking of the diseased area, but by a decrease of inflammation, the original area remaining the same in extent until the return to the normal state is effected. 6. The eruption has a tendency to frequent relapses, for which often no immediate cause can be ascertained; and this in spite of the most careful attention.

The diagnosis must be made between this form of eczema and the following: 1, Parasitic eczema; 2, irritative or "trade eczema;" 3, chronic circumscribed eczema; 4, gouty or rheumatic eczema; 5, seborrhœic eczema when well developed; 6, eczema marginatum or ringworm.

The presumptive diagnosis is based on the signs and characteristics enumerated above.

The differential diagnosis will be taken up in the order of importance.

1. The form of eczema most likely to be mistaken for the one under discussion is that known as parasitic eczema, due to the action of a number of minute organisms on certain circumscribed areas. In this form we also find patches of diseased skin sharply defined, but there is no symmetry of location observed. The patches are irregular in shape, not composed of aggregations of papules or vesicles. The periphery shows, instead of a raised border of papules, undermined epithelium. Infiltration of the patch is rare. The eruption spreads by enlarging of separate patches, which is accomplished by undermining the epithelium, a distinctive sign. No pe-

culiar location is observed, though it occurs usually on exposed surfaces, as on the hands.

2. Irritative and trade eczemas are due to irritants; the affected area is usually circumscribed, though not confined to patches, and the borders of the eruption are not sharply defined, but fade gradually into healthy skin by the papules becoming less thickly set. A history of previous irritation is always obtained.

3 In chronic circumscribed eczema there is usually a history of a previous acute outbreak involving a larger surface than that now affected. The periphery is not sharply defined. The patch is usually large and single. It may involve both sides of the body, but symmetry, if present, is accidental. Usually it is the flexor surfaces of the joints that are involved.

4. Gouty or rheumatic eczema is usually unilateral, the patch is large and irregular and very much irritated. In case of spread of the disease, the patch enlarges peripherally. There is a history of gout or rheumatism, and often there are enlarged metacarpal joints. The urine is scant and shows excess of urates.

5. Seborrhœic eczema when well developed is patchy in character, the edge being well defined but not composed of vesicles or papules. The crusts, if any, are in this case greasy to the feel, and brittle. The disease presents a history of slow development, commencing with pityriasis or dandruff on the head, and developing from above downward. There is in seborrhœic eczema no symmetry of location, and the points most favored are the scalp, face, and chest, sometimes the groin and axillæ.

6. Eczema marginatum is merely an irritated and extensive ringworm usually found around the buttocks and groin. There are patches with rather sharply defined edges, but the history is always that of a small area of ringworm at first, and subsequent spread of the eruption with clearing in the centre. The edge is constantly advancing.

The treatment should be both internal and local. The internal treatment should be directed first toward correcting any functional disorder present. To this end we should submit our patient to a careful examination and questioning. As a hygienic measure, the nervous system should be relieved as far as possible from any disturbing influence, such as mental worry, business cares, etc. To this end perfect rest and cessation from business or household cares should be enjoined. The patient should have at least one free movement of the bowels every day. Any existing digestive trouble must be corrected. Every organ should be examined to determine the existence of reflex influence, and any disorder of the reproductive organs that may be present must be corrected. Tonics should be administered to strengthen the inhibitory powers of the nervous system and to improve the nutrition of the whole body. Phosphorus and strychnine are probably the best remedies for fulfilling this indication.

Acting on the theory of the vaso-motor disturbance as a cause of the eruption, ergot was given in several cases with splendid results. Although I have not yet tried it, I am inclined to think that the galvanic current to the spine would be of benefit. Local treatment should be governed entirely by the condition found.

I give below a few combinations that have proven useful in practice. For weeping eruptions a nygroscopic lotion is necessary, and for this purpose I prefer the following combination:

℞. Magnesii carbonatis,
Pulvis zinci oxidi.....āā ʒss. to ʒj.
Aquæ rosarum..... ʒiv.

There is a lotion somewhat similar to this in which calamine is substituted for the magnesium carbonate, but I have found the calamine to be always more or less irritating. In the dry forms, with slight scaling and induration, I use one of the following:

℞. Acidi salicylici..... gr. v. to gr. xv.
Ung. zinci oxidi..... ʒj.
M. Sig.: For external use.

℞. Ung. picis et zinci ..... q. s.
Sig.: External use.

℞. Ichthyol..... gr. x. to gr. xxx.
Ung. zinci oxidi..... ʒj.

In those cases where the congestion is marked, ergot gives good results applied locally in the form of an ointment, or the fluid extract may be advantageously combined with any of the above formulæ. Where the induration is very marked the unguentum picis et zinci is very good.

It is unnecessary to give further details. It would seem to be sufficient to sketch out a line of treatment, since the conditions of each case of eczema are always varying and each condition must be treated according to circumstances.

434 Penn Avenue. Pittsburg, Pa.

Clinical Department.

A CASE OF VAGINISMUS.

By ALBERT KROG, M.D.,
NEW YORK.

About five months ago Mrs. N. M—— called upon me, from New Jersey, with the following history: She had been married five months, had always enjoyed perfect health, although she was of a somewhat nervous disposition and anæmic. Quite soon after her marriage coition had become impossible. The accompanying pains were something intolerable at first, making, as stated, coition entirely impossible. There was no discharge, no leucorrhœa; defecation and urination were without pain and regular, appetite good.

Upon my request that a thorough examination of the parts locally would be necessary, she gladly consented, but doubted the possibility of a digital examination. As she lay upon my operating-table, inspection showed nothing but a slight œdema and redness of the external parts. Upon my attempt to introduce my index-finger, the muscles of the floor of the pelvis became suddenly perfectly rigid; the muscles of the thighs began to contract spasmodically, the patient cried and complained that I was causing her the most agonizing pain. No amount of persuasion could induce her to become more quiet or calm, and as she became more and more hysterical I was compelled to desist from all further examination.

I had not even been able to separate the labia, nor had I been able to see the hymen or what was behind it.

A second examination, a week after, was even less successful than the first. The pains had grown more intense, the parts so hyperæsthetic that even the clothes coming in contact produced great agony. Her condition was deplorable, and her marriage life was far from being a happy one.

There was no doubt that the existing symptoms were those of vaginismus, the cause of which I had not as yet been able to detect. Consequently it was considered best to anæsthetize her and act at once according to the existing lesions.

My friend Dr. Waechter kindly administered the chloroform. When perfectly under its influence, and the parts had thoroughly relaxed, my finger entered the introitus vaginæ without the least resistance. The uterus and vagina were explored, but nothing abnormal could be detected.

Nevertheless, a close ocular inspection revealed the following conditions: The hymen had been lacerated into four distinct parts, each of which was more or less triangular in form. On the apices of each of these a small hypertrophic nodular mass (like corns on the feet), of the most extreme sensitiveness, was detected. Naturally I resorted at once to the excision of the entire hymen. There was but little hemorrhage; the resulting raw surface was left to cicatrize. A tampon of unguentum iodo-

formi was inserted into the vagina, large enough to distend the entire cavity thoroughly. Calling upon my patient the next day, I could realize at once the success of my operation as expressed by her countenance.

She could change the tampons and irrigate the parts with but very little annoyance, except, as she states, a feeling of slight soreness. The introduction of tampons was continued for about ten days longer. The small wounds healed admirably. There was no more pain. She is now pregnant.

THE POWER OF SULPHATE OF MAGNESIUM IN CURING CATARRHAL INFLAMMATION OF THE DIGESTIVE TRACK.

By S. BRADBURY, M.D.,

OLDTOWN, ME.

Thirty years ago I was treating an infant, aged eighteen months, that had dysentery. My treatment was strictly according to the medical works of the time, but the child did not improve. I treated it about two weeks, when the mother, as well as myself, got disgusted, and she called in a quack, who treated it about a week, when the mother again called me to attend the patient. I found it worse than ever, having bloody, slimy discharges every twenty minutes. A good angel told me to give the child a big dose of "salts." I did to the extent of a heaping teaspoonful. I trembled as to the result, as the patient was very weak, but seeing the mother a few hours after the medicine was given, she told me the child was white as a sheet when the medicine operated, but had had no more bloody discharges since then. In fact, this one dose of sulphate of magnesium cured the infant, so it was not necessary to give anything more whatever in the way of drugs.

When travelling in Palestine, in 1870, one of our party, Mr. C——, of New York, was laid up several days in Jerusalem with dysentery. He was so sick that he could not go with us to Tiberias. Before leaving him I went into an Arab drug store and asked for a quarter of a pound of sulphate of magnesia, got it, and gave the patient a very large dose, that is, as much as I could get on to a great spoon twice, to be repeated every day until the disease was cured. On my return to Jerusalem, a week or more afterward, the patient told me the medicine I gave him very soon cured him, and that he was as well as ever

About fifteen years ago I was taken with severe inflammation of the three inner coats of the small intestines, viz., mucous, areolar, and muscular; for I had frequent violent griping pains, with bloody and slimy discharges, evidently coming from the small intestines. I commenced treatment with a cupful of clear salts dissolved in water, which operated in about an hour, but this dose did not give the perfect relief that I expected. I therefore took half a pint more of clear salts dissolved in water, one hour from the first dose. This last dose wiped away the inflammation as if by magic when it operated, and left not a trace behind.

Ten years ago, coming home from a journey, I found an old patient of mine who had been laid up several weeks with severe inflammation of the stomach, to wit, gastritis, the peritoneum not being involved. She had been attended by a homœopath for a week or more, with no benefit. I immediately gave her a very large dose of salts, the exact amount I have forgotten, but the patient was up in three days doing her work.

I have thus given three cases of inflammation of the three innermost coats of the large and small intestines, and also of the stomach, to show the power of salts to cure. The infant cure first mentioned opened my eyes very wide to the great value of sulphate of magnesium in catarrhal inflammation of the stomach and bowels, and I could fill many pages of your journal in giving instances of cases cured by it. Whether this medicine is adapted to the treatment of peritonitis I do not know, as I never dared to use it in this disease, but I notice a Liverpool physician, Dr. Hunt, speaks very highly of it here too.

Now, one word in regard to the dose of sulphate of magnesium in the above cases, and I will close.

I have found, in a large experience in using this salt, that small doses do more harm than good. The smallest dose for an infant should not be less than a heaping teaspoonful, and a great spoonful may be given without harm. The truth is, the greater the dose the less it gripes. In my case above, I took half a pint of clear salts dissolved in water without the slightest griping when operating. This medicine does good in the cases mentioned, evidently by producing a copious discharge from the lining of the digestive track, without having any but the slightest effect upon the muscular coat. It is totally unlike ordinary cathartics, it simply causes the excretion of fluids from the digestive mucous membranes, hence the safety in giving large doses, as the intestinal muscles are not acted upon by them.

AN UNUSUAL CASE OF PNEUMOTHORAX.

By FRANK H. MURDOCH, M.D.,

PITTSBURG, PA.

On Monday, March 28, 1892, I was called to see a patient with the following history:

Miss D——, aged fifteen, who had always enjoyed good health and whose family history was good, had, during the night, suffered from a quite severe pain in her left side. At the time of my visit the pain had disappeared, and I could discover nothing wrong about the chest excepting an exceedingly tender spot as large as the hand below the left scapula.

On Tuesday I did not see her. On Wednesday, while being raised in bed, pressure was accidentally made on the tender spot in the back, and she was immediately seized with a severe paroxysm of coughing, which lasted ten minutes, and which completely exhausted her. I saw her soon after the attack and found her lying quietly in bed, apparently perfectly comfortable. Her pulse was 110, her temperature 100½° F., and her respirations 22. There was no pain or dyspnœa.

Examination showed that over the whole of the left chest, excepting near the spinal column, there was absence of vocal fremitus, hyper-resonance on percussion, with metallic voice and metallic tinkling on auscultation. The heart was so much displaced that the valve-sounds could be distinctly heard only to the right of the sternum. The treatment consisted in regulating her diet and keeping her quiet in bed. In four weeks the air had disappeared from the pleural cavity and the heart had resumed its normal position. The lungs were left none the worse for the attack.

The points of special interest in this case are, first, what caused the rupture of the pleura, and second, air having entered the pleural cavity, why was there no dyspnœa? That the severe paroxysm of coughing was the immediate cause of the rupture of the pleura there can be no doubt, although in the absence of tubercular disease of the lungs there was no good reason why the pleura should have ruptured from so slight a cause. The entire absence of dyspnœa is also not easily accounted for, and is entirely unusual.

Fraentzel[1] writing on this subject says: "In a not inconsiderable number of cases there is no dyspnœa, but these are always in very debilitated individuals generally suffering from advanced phthisis."

Allbutt[2] says: "In those rare cases in which pneumothorax comes on apparently as a primary disease, that is, in which the entrance of air into the pleural cavity is obscure, we find the chief symptoms to be dyspnœa and a sense of faintness."

Had the pneumothorax been limited by old, strong ad-

[1] Ziemssen's Cyclopædia, vol. iv., p. 755.
[2] Quain's Dictionary of Medicine, p. 1225.

hesions, there might have been but slight pain and no dyspnœa,[1] but in that case there would have been only partial dilatation of the chest, and the heart would not have been displaced.[2] In looking up the subject I can find reports of but two similar cases. One is by Fraentzel [3] and the other by Symonds.[4] Both patients were healthy men. One man was rolling a heavy barrel at the time of the attack, and the other was working inside a fire box. Both experienced great dyspnœa, and both made good recoveries, one in six weeks and the other in two months, without any pathological changes having taken place in the lungs.

It would seem, therefore, that when rupture of the pleura occurs in apparently healthy individuals, the opening soon closes, while in cases of pneumothorax, the result of tubercular disease of the lungs, the perforation is very likely to remain open to the end of life.[5]

ABSOLUTE REST OF THE PARTS THE BEST TREATMENT FOR LESIONS OF THE VOCAL CORDS.

By JOHN TRAILL GREEN, A.M., M.D.,

TUCSON, ARIZ. TER.

The varied experiences of four years in a well known health-resort for lung and throat troubles have convinced the writer of the assertion conveyed in the title to this article: "If any lesions of the vocal cords or adjacent parts of the larynx are discovered, absolute rest of the parts is the best treatment." Certainly not to the exclusion of other remedies, well known and proved to be potent, but to be insisted on, no matter what be the medicinal treatment or the climatic surroundings. Anyone who has closely watched such cases has observed the dry, hacking, laryngeal cough that is sure to follow over-use, or indeed any use of the voice, be it singing, loud talking, or only whispering. Some patients, and, in fact, some prominent physicians, have an idea that what is called "whispering" does not irritate the cords, and may be allowed. If one watches a patient closely he will soon see that the so-called whispering (especially when trying to make the sound carry some distance) is even more of a strain than the use of the voice at its natural tones. And it will also be noted that the same short, dry, laryngeal cough is almost invariably brought on. Again, if we examine a larynx after the patient has over exerted the cords by the so-called social or domestic duties that invalids insist must be carried out, we are sure to find any ulcers irritated, any congestion worse, and patients themselves can easily feel the increased pain. It is certainly not pleasant to give up the use of one's voice, but could we make patients fully understand their condition, and the value of such a procedure, they would soon agree with us. What does one year's talking amount to compared to fifty or sixty of future life and usefulness if a cure can really be accomplished? With the fewest possible exceptions such patients are young—under thirty—and have the best part of their life before them. Only within the last year the writer has tried to impress upon at least twenty patients the value of absolute dumbness. Success has been obtained completely in only one case, and with results that put the others to shame for the lack of will-power to stop talking. True, many others have come near the mark, but will keep up more or less useless irritation. One great difficulty is the extreme sensitiveness to being thought an invalid; when, as a matter of fact, no one cares to disguise such a fact from their friends, why should they care for the stranger? In reality, does any invalid disguise his or her condition from an observant person? The writer has never happened to see this absolute rest so strongly insisted on before, and wishes to emphasize its benefit to the profession. Point out the necessity to each patient and appeal to their will-power to help you, but especially to help them. In conclusion, it may be added that one patient out of the twenty who had the nerve to stick to his conviction of the benefit of this rest was a physician in active practice, who carried on his professional work by means of slate and pencil. His experience as to the relief of pain, the cessation of cough, and the general improvement of vitality are enough to convince one of the utility of the treatment. If the idea is of any use, it is much more so as the first symptoms appear. Let us make it an axiom in every case of laryngeal trouble, however slight, to insist on "absolute non-use of the voice."

A CASE OF MALIGNANT TUMOR OF THE FEMUR IN A BOY AGED THIRTEEN YEARS, OCCURRING IN THE PRACTICE OF E. J. SMITH, M.D.

REPORTED BY F. OVERHOLT, M.D.,

HARLAN, IA.

C. N——, while riding horseback in Idaho, in August, 1891, struck his knee against a sapling, but no symptoms followed at the time.

Dr. Smith first saw the case on November 22, 1891. It had then all the appearances of a simple synovitis, which was controlled by extension and application of hot water. Four weeks later it began to swell above the knee, the swelling being accompanied by pain, and subsiding at times.

On January 1, 1892, fluctuation became so apparent that an incision was made into the joint at the lower edge of the tumor, to the outer side of the patella. No pus was found, but there was very severe pain now all the time. Next week the joint was opened again on the other side, higher up. No pus, but some broken down tissue was discovered. On January 11, 1892, the patient had a chill, and the following day Dr. Smith, assisted by Dr. E. B. Moore and myself, performed circular amputation in the upper third, in what appeared to be healthy tissue, muscle and bone seeming all right.

The operation was finished hurriedly on account of shock, and the patient was put to bed, surrounded by hot bottles. He did not rally well, and did not regain complete consciousness till the next morning. At 6 P.M. the temperature was 104° F.; at 12 midnight, between 105° and 106° F. The following morning the temperature was 99°, and from this on stayed below 100° F., and the patient's general health improved slightly.

We had four inches of flap after the leg was off, yet two weeks after the bone emerged from the stump in spite of adhesive straps, etc. The fatty tissue to be spoken of later broke down and came away, which in a measure accounted for the retraction. Later, healthy granulations sprang up and covered the bone, and we were in hopes the boy would get well; but by February 20, 1892, there was well-marked return of the disease in the stump. The growth extended up into the abdomen, as well as increasing the size of the stump, until, when the patient died, on March 10th, it measured twenty-three inches in circumference.

The features of interest in the case to us are: 1. The rapid growth. 2. A deposit of very yellow fat, half an inch thick over the whole leg, although the other leg or thigh was so thin that one could reach around it with the hand. This fat broke down and came away from the stump. 3. The cartilage of the articular facets of the femur and tibia seemed sound, although just above the condyles of the femur a scalpel could be easily run through what was left of the bone. 4. The entire tumor was black and gangrenous when removed.

The Danger of being a Good Samaritan.—A French court has decided that the person who summons a physician to see a sick person is responsible for the payment of his fees.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 9, 1892.

SEXUAL BRAIN DIFFERENCES AND HIGH-SCHOOL EDUCATION.

EVERY now and then the dangers of educational overpressure are portrayed in more or less vivid colors and set off with sombre statistical backings. Some wholesome truths are no doubt furnished in these jeremiads on modern education; but we believe that these truths should be allowed only their due weight, and should not lead to the conclusions too often drawn, that our methods of training the young are entirely ill-directed and pernicious.

Sir J. Crichton Browne is the latest of the alarmists, and he starts well back in his argument by adducing facts to show that the female brain is relatively smaller than the male, and that its blood-supply is more richly distributed to the posterior portions and lower levels of the encephalon. Regarding the first point, facts of some interest are cited.

Dr. Browne does not know of any trustworthy standards of the brain-weights of healthy natives of Great Britain, but he gives a table showing the brain-weights of sixteen hundred insane persons, mostly English, which he says is absolutely reliable. This table deserves incorporating here.

Sexes.	Average weight of brain.		Average height.			Excess of male over female brain-weight.		Excess of male brain-weight after allowance for height.	
	Gms.	Ounces.	Metres.	Feet.	Inches.	Gms.	Ounces.	Gms.	Ounces.
945 Males . . .	1350.54	47.64	1.702	5	7	127.68	4.50	29.71	1.05
655 Females . .	1222.86	43.14	1.575	5	2	....	....	....	....

It shows that, after making all allowances, the female brain (of the insane) weighs at least an ounce less than the male. The fact that the brains weighed were those of the insane makes the figures come out rather more favorably to women, in Dr Browne's opinion, since organic disease which causes brain atrophy is much more frequent among insane males. To this, however, it may be said that the observations of Dr. Bra on the weight of the insane brain, show that the sexual differences in mania and melancholia are greater than normal, and that there are decided variations depending upon the form and stage of the insanity. Laufmauer also, who examined and weighed 656 insane brains, found a sexual difference of 153 grammes as against the normal difference of 143 grammes. The conclusion drawn by this writer, as well as by Parchappe and Meynert, is that in insanity the female brain suffers twice as much as the male. We cannot therefore regard Dr. Browne's figures as at all conclusive.

With regard to the relative weight of the healthy female brain, there has been a general agreement among brain anatomists as to its inferiority. Still Bischoff, who has contributed perhaps the most elaborate study of the subject, states that, relative to the body-weight, the female brain is the heavier.

Dr. Browne's next sexual difference in the brain is a more voluminous posterior development. This has been sufficiently proved by facts which he does not seem to be aware of, viz., cranial measurements. The cerebellum and the occipital lobe are both relatively larger in women.

A third sexual difference which Dr. Browne alleges to exist is that of diversity in convolutional arrangement and in weight of the cerebral hemispheres. He thinks that woman's convolutions have a simpler pattern, and that her left brain weighs relatively less as compared with the right. It is generally admitted that in healthy brains there is no essential and permanent difference in weight between the two hemispheres. Hence the sexual differences found by Dr. Browne in the insane can have no value as applied to the healthy. Nor can any be attached to such a general statement as that the convolutional arrangement is simpler in woman. The differences as regards this point in men are very great.

A final point made by Dr. Browne is, that he has found that the internal carotid and vertebral arteries, when measured separately, display a marked difference in calibre in male and female brains respectively. "In ten male brains," says the writer, "of adults free from brain disease, and ranging from twenty-five to thirty-six years of age, the internal carotid arteries had an average diameter of 2.8 millimetres on the right side and 2.75 millimetres on the left side; while the vertebral arteries had an average diameter of 2.2 millimetres on the right side and 1.875 millimetre on the left side; whereas in ten female brains of adults free from brain disease, and ranging from twenty-five to forty three years of age, the internal carotid arteries had an average diameter of 2.6 millimetres on both sides, while the vertebral arteries had an average diameter of 2.3 millimetres on the right side and of 2.075 millimetres on the left side. It thus appears that the distribution of the blood in the male and female brain, respectively, varies to a considerable extent. The internal carotid arteries, with their great branches—the anterior and middle cerebral arteries supplying the supra-orbital convolutions and island of Reil, the gyrus fornicatus, the Rolandic area, the angular gyrus, and the first temporo-sphenoidal lobule—are much larger, both absolutely and relatively, in the male than in the female brain; but the vertebral arteries which supply the occipital and temporo-sphenoidal lobules are larger in the female than in the male brain, and the basilar artery, which is practically a continuation of the vertebrals, is also larger in the female brain, where its average diameter is 2.8 millimetres, than in the male brain, where its average diameter is 2.675 millimetres."

The above figures, though based on very few observa-

tions, are of interest, and might have been supplemented by the fact that in apes the vertebral nearly equal the internal carotids, while in man they are relatively smaller, so that their union in the basilar makes a single artery about the size of the carotid. On the other hand, what will Sir James do with the fact that in over five per cent. of cases the posterior cerebral arteries come from the carotid?

On the whole, one can hardly say that Dr. Browne has added anything positively new to our knowledge of the sexual differences of the human brain.

It is not denied, however, by anyone that such distinctions exist, and, after all, the important part of the paper is that which deals with the practical question of the education of girls. Dr. Browne attacks the high-school system of England. He asserts that in furnishing a higher education for woman, it hurts her physically and mentally. He finds that in one school, among 187 girls, 137 had headaches. He also shows by statistics how sensitive to morbific influence is the system of the adolescent female.

We cannot venture to criticise the educational methods of English high schools. They may teach wrong things and in a wrong way; but surely any person who denies the usefulness and propriety of giving girls a high education if they want it, is too far lacking in sense to deserve serious consideration. It is quite possible for woman to know something and yet be lovely. If knowledge extinguishes beauty in England, it must be the fault of the method, not of the knowledge. If the high school of England, as Dr. Browne thinks, makes the female leg thin, the bust flat, and the eye myopic, it truly needs reform; but such is not the necessary result, nor have such disastrous illustrations of anatomical astringency befallen the high-school work of America.

TYPHOID FEVER IN CHICAGO.

We printed with great pleasure, a few weeks ago, a letter from Dr. Ingals, of Chicago, in which the writer stated that the sanitary condition of that city was far better than had been represented, and that all danger of contamination of the water-supply would soon be entirely removed. We are sorry now to learn, on the authority of the Chicago *Herald*, that the danger still exists. The city sewers discharge into the Chicago River and the river empties into the lake. The water supplied to the city is drawn from a point in the lake said to be two miles from the shore, but yet in the path of the current from the river, and is directly contaminated by the sewage carried by this current. According to the *Herald*, "forty million gallons of diluted sewage" are added daily to the drinking-water of the city. With a population half a million less than that of New York, the deaths from typhoid fever in Chicago in 1891 were over five times as many as in this city, the figures being 1,997 for Chicago, and 384 for New York.

Such a showing would be disgraceful to the capital of Kurdistan or Mecca, but when we consider that it relates to the second city in America, and to a community that has invited the whole world to visit it next year, it is little short of incredible. If it were not for the World's Fair this matter would be of less interest to the rest of the country. We might look on with wonder that any community could exist in this enlightened age having so little regard for the lives of its members, but we should feel that it was for Chicago to work out its own salvation, and our duty would be ended with a warning to travellers who were not bent on suicide to keep away from the place.

But it is different now. This country has extended an invitation to all the nations of the earth to visit the city by the lake in 1893, and it is as much our duty to protect our guests from pestilence as it is to guard them against the assaults of highwaymen. Chicago, in securing the holding of the Exposition, has assumed responsibilities which the rest of the country must see that it does not shirk, and the chief of these responsibilities is the safeguard of the health of the strangers who are invited to visit it. It would be far better to call a halt at once, revoke all invitations to foreign exhibitors, recall the commissioners who have been sent abroad, and demolish the buildings already erected, rather than expose confiding visitors to the horrors of an epidemic.

It is said that new pumping-works will soon be in operation which will force all the city sewage into the Illinois River, leaving the lake water absolutely pure. It is very evident, however, that those works are not yet in operation, or if they are, that they fall very far short of accomplishing what was expected of them.

It is an unpleasant duty to expose the shame of a city to which the eyes of the whole world are turned, but the matter is one that vitally concerns the honor of our country, and it would be little short of criminal to belittle such a real and present danger. We can but trust that our Chicago friends have a firm foundation for the hopes they continually express of a betterment of the sanitary conditions of their city, and none will be more glad than ourselves to announce that the time has at last come when one can go to Chicago without taking his life in his own hands. May the country not have long to wait before receiving these reassuring tidings.

SCIENCE AND WOMAN.

Professor William James, of Harvard, announces that woman develops early and then ceases to grow mentally. Professor Crichton Browne finds that women's brains are smaller than men's, and their frontal lobes less richly supplied with blood. Professor Lombroso finds that women are less sensitive than men, and, as regards their receptive and perceptive organs, represent an incompletely developed type. Altogether science is bearing down very hard on the ladies. Yet we do not learn that they are becoming any the less popular. The poet has said metrically that without them the extremes of life would be without solace and its middle without joy. The testimony of the poet will probably continue to be received by the mass of humankind, even if the greatest cranial circumference of the gentle sex never rises above fifty centimetres.

The Sultan of Turkey is said to be suffering from pulmonary phthisis. His mother died of the disease, and he developed symptoms of the incipient affection when quite a young man, but was supposed to have been entirely cured.

THE MYSTERY SOLVED.

One of the most difficult things in all this world to explain is individual idiosyncrasy, and we are therefore greatly pleased to inform an expectant world that one mystery of this kind has been satisfactorily cleared up. In a recent note we referred to the strange fact, if fact it be, that Mr. Gladstone chews every bolus of food just thirty-two times, and ventured the query why it should be thirty-two instead of any other number. This has been answered by a number of friends, who say that he makes one masticatory effort for each and every tooth that is, or ought to be, in his head, piously remembering the absent ones and making those that remain do duty for any that may have fallen by the way. This explanation is, we think, satisfactory, and we hope that the Grand Old Man will, for his stomach's sake, continue to make each tooth do its full duty, and not allow his watchfulness to relax in the excitement of reading election returns or when worried by missiles cast at his head by a ribald populace.

AËRONAUTIC CASUALTIES.

Two drowned, two nearly drowned, one with a broken rib and probably internal injuries, and one who was saved from injury or death by falling into a tangle of telegraph wires. That is the, doubtless incomplete, record of accidents to aëronauts on Independence Day. In addition to this, a baby, whose mother was watching the ascension, was nearly decapitated by the rope dangling from a rising balloon. The impatient, whose ears were tickled last summer about twice a week with the dull thud of some balloonatic striking the earth, may think this is a small number, but they must make due allowance for the fact that it is only the beginning of the season, and that the parachute fiend has not yet commenced to tumble. The latter will begin soon, no doubt, for it is too much to believe that all of his race were killed off last year, and each one as he falls will contribute his mite toward the raising of the mortality list.

News of the Week.

City Hospital, Blackwell's Island, New York.—Dr. Frederick H. Wiggin has been appointed a member of the Medical Board of the City Hospital, Blackwell's Island, *vice* Dr. Ferguson, resigned.

The Micro-organisms of Cancer.—In an article on cancer of the pancreas, Dr. Simon Flexner (*Johns Hopkins Bulletin*) describes the results of his investigation of the so-called organisms or "coccidia" of cancer. He concludes: "We have no difficulty in reconciling the appearances which we have described with those of many writers on the psorospermic origin of cancer and some other affections. Indeed, it is even possible to see in the variety of form and number some of the stages of development which they have depicted. We do not, however, regard these bodies as organisms, but rather interpret them as being degenerations occurring in cells and nuclei, affecting, as a rule, not the whole of these, but circumscribed portions. The observed differences in density, granulation, and homogeneity may, perhaps, be accounted for on the supposition that they depend upon different degrees of one process, or represent different ages. The presence of stained particles within many of them, however, is not so easily understood in those instances where the nuclei of the cells are intact. It may be well to suggest the possibility of their being leucocytes which have wandered into the necrotic parts of cells, as leucocytes are known to enter dead cells in other cases. Some of the stained particles suggest the nuclei of polynuclear leucocytes, while in other cases it is possible to see in the irregular particles what correspond to fragments of nuclei, probably derived from those leucocytes which have perished after having entered the degenerated bodies."

Pilocarpine Hydrochlorate hypodermically, conjoined with the internal use of camphor, is reported to have excellent results in *status epilepticus*.

Ammonium Benzoate, in 5 to 15 grain doses is considered by Dr. Steer about the most satisfactory medicament in cystitis.

The Local Examination of Unmarried Women.—Commenting favorably on the excellent article of Dr. Coe (*Med. and Surg. Reporter*), the editor of *Gaillard's Medical Journal* says: "In the discussion of a recent able paper of Dr. A. Jacobus on amenorrhœa before the Northwestern Medical and Surgical Society, the consensus of opinion seemed to be that local treatment was unavailing in most cases, and several able observers inveighed against the too common practice of vaginal examination of young girls. The writer's personal observation may serve to enforce this view. He has occasion to treat a large number of young lady teachers. Recently two of these have consulted him who have been treated by 'lady physicians.' It appears from their statement that many of their friends have been subjected like themselves to tri-weekly applications of tampons, iodine, pessaries, etc. In both cases there was no organic disease requiring local treatment. One had become a utero-maniac, whose chief symptom was vomiting and loss of appetite. Placing her under strict surveillance in the hospital and giving her daily cold ablutions, with tonics and absolute abstention from local treatment, restored the stomach. She gained flesh and went to work. But her utero-mania had been so firmly established that she applied at a dispensary, where the young gynecologists treat her anteflexure secundem artem (?). The other case was found to be suffering from constipative anæmia and neurasthenia. Being a woman of great will power she has abandoned all thought of local treatment, and is now gaining health and strength under the rain-bath, and daily ablutions, aloes and mast pills, and good diet. It is our duty to save these young girls the mortification and annoyance, and absolute injury of a vaginal examination unless found absolutely necessary, after failure of other treatment. To our colleagues of the gentler sex this duty is quite as imperative, and their attention to it is the more necessary, since they may regard the moral effect less pronounced, and many of them deem themselves specially adapted to this class of practice among young women."

Incompatibles of Antipyrin.—The *Pharmaceutische Centralblatt*, No. 29, 1892, gives the following incompatibles of antipyrin which precipitate the antipyrin from a

concentrated solution: 1, Concentrated solution of carbolic acid; 2, tannic acid, and preparations containing it; 3, tincture of iodine; 4, the chlorides of mercury. The following substances also decompose antipyrin when triturated with it: 1, Calomel forms with antipyrin a toxic combination; 2, antipyrin is decomposed when rubbed with beta-naphthol; 3, with chloral antipyrin forms an oleaginous liquid; 4, with bicarbonate of sodium it disengages the odor of ether; 5, salicylate of sodium, equal parts with antipyrin, forms an oleaginous mixture.

A Post-Graduate Hospital and College has been organized at Albany, N. Y. It is to be called the Sydenham Post-Graduate Course and Hospital.

The Annual Address in Medicine before the Medical Faculty of Yale University was delivered by Dr. George M. Sternberg, U.S.A., on the "Etiology of the Infectious Diseases, and the Explanation of Acquired Immunity from these Diseases," in Battell Chapel, New Haven, Conn., on Tuesday, June 28th.

Dr. George W. Jarman has been appointed Obstetric Surgeon to the New York Maternity Hospital, to fill the vacancy created by the resignation of Dr. H. J. Garrigues, who has been made Consulting Surgeon.

The Paterson General Hospital.—The new building of this institution was opened for the inspection of the public on Saturday, June 18th. The dedicatory services were held in the afternoon of that day.

Scarlet Fever in London.—The cable reports that scarlatina is more than usually prevalent in London, the hospitals which can receive cases of that nature being so overcrowded that temporary huts are being erected for the accommodation of patients. About two thousand five hundred cases were under treatment in hospital on July 1st, and the number of children under treatment in their homes was also very large.

Dr. James S. Green, of Elizabeth, N. J., died at his home on July 2d, of heart disease. He was born at Princeton in 1829, and was educated in medicine in Philadelphia. He had resided in Elizabeth since 1853.

Dr. W. B. Green was killed at Long Branch on July 1st. He was crossing the railroad track and was struck by the locomotive of a passing train and instantly killed. It was raining heavily and Dr. Green was carrying an umbrella in such a way that he could not see the approaching train.

The Cholera is advancing from Central Asia into Europe. It has entered Russia at Baku on the Caspian Sea, and has travelled eastward as far as Tiflis. Passengers from Central Asia on the Trans-Caucasian railway are quarantined for three days near Baku and forced, much against their will, to take a bath and change their clothing. The transportation of freight on the railway has been forbidden, and all food brought into the country is carefully inspected. The disease has appeared also at Astrakhan, and thence ascended the Volga to Saratov. The latter city is on the direct line of the trade route between Asiatic Russia and Moscow, and it is feared that nothing can prevent the epidemic invading this city in the very centre of the empire. The Russian authorities are reported to be doing the best they can to keep the disease back, and to enforce the observance of sanitary laws. Cholera has also appeared in Italy, five cases being reported at Brindisi, the terminus for most of the steamers plying between the Levant and Europe. A cablegram from Paris, dated July 6th, reports that there were twelve deaths from "cholerine" in the various suburbs of that city on Tuesday.

The Late Dr. Birdsall.—At a meeting of the Lenox Medical and Surgical Society, held on June 20th, the following preamble and resolutions were adopted:

Whereas, This society has in the death of Dr. W. R. Birdsall sustained the loss of a most valued member; therefore,

Be it resolved, That the Society express the profound sense of bereavement which it has sustained, and that its sympathy and condolence be extended to the family of the deceased.

Resolved, That a copy of these resolutions be furnished the MEDICAL RECORD and the *New York Medical Journal* for publication.

Signed, J. LEE MORRILL, M.D.; S. S. JONES, M.D.; J. BLAKE WHITE, M.D.

Increase in Number of Physicians in New York.—*The Medical Register* for 1892 contains the names of 6,651 physicians practising in New York City and State, as against 6,268 one year ago. In this city the list includes 2,435, as against 2,328 in 1891. Besides this registered number, it is stated that there are about 870 physicians practising more or less irregularly, of whom over 100 are known to be advertisers. The total number of physicians in New York must be about 3,300, and in Brooklyn about 1,000. This gives one physician to 500 population in New York, and one to 900 in Brooklyn. The relative number of physicians throughout the State is less than in the large cities. Attention is called to the fact of the large increase in the number of dispensary patients of late years. In 1891–92 there were 442,000 cases treated gratuitously, or nearly one third of the population. We observe that the editor of the *Register* continues to omit from the list of physicians prominent and reputable men who are members of the New York Academy of Medicine.

The Langenbeck House, which is the name of the new medical building at Berlin, was recently opened with appropriate ceremonies. It contains a lecture theatre with seven hundred seats, where Siemering's bust of Langenbeck is to be placed, a room for meetings arranged for several hundred persons, a fine reading-room, an elegant *foyer*, which is to be ornamented by the bust of the late Empress Augusta (the gift of the Emperor), and by life-size portraits of the present Emperor and Empress; rooms for scientific collections, etc. The entire cost of the building, including site, has been 550,000 marks (£27,500). The *Deutsche Medizinische Wochenschrift* has published a special surgical number in honor of the inauguration of the Langenbeckhaus. Among the contributors are Czerny (Heidelberg), Trendelenburg (Bonn), Schede (Hamburg), Kümmel (Hamburg), and their papers are followed by reports from the surgical clinics of Berlin, Marburg, and Kiel.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH.

Eighth Annual Meeting, held in Brooklyn, May 24, 1892.

In the absence of the President (Dr. Henry Van Hoevenberg, of Kingston, Ulster Co.), Dr. William T. White, the New York County representative on the Executive Committee, occupied the chair. At the morning session a biographical sketch of the late Dr. Lucius Damainville, written by Dr. Austin Flint, was read by the Secretary, Dr. E. H. Squibb, of Brooklyn, and a sketch of the late Dr. David Matthews by Dr. S. B. W. McLeod.

Therapeutic Efficacy of Saratoga Waters.—Dr. T. Herring Burchard then read an exhaustive paper on this subject. He stated that it represented an experience extending over sixteen years and many hundreds of cases. The paper was devoted to the consideration of these principal points: 1, The real merit of the waters as indicated by their chemical properties and physiological effects; 2, the relative value of the principal springs in different classes of affections; and 3, their practical utility in the treatment of disease. The greatest misfortune from which Saratoga suffered, he said, was an embarrassment of riches, the great number of its springs and the great variety of their chemical composition. The Congress, Hathorn, Geyser, and other springs furnished ideal saline cathartic waters. One notable characteristic of the Saratoga waters was the large amount of carbonic acid gas they contained, especially when they were compared with the famous mineral waters of Europe. The two most prominent alkaline waters were the Saratoga Vichy and the Saratoga Carlsbad. While the French Vichy was more alkaline, the Saratoga was superior on account of the character of its constituents. It was much richer in lithiates of calcium and magnesium, while the quantity of carbonate of lime was remarkable. Hence it was a very valuable agent in the treatment of lithiasis, gout, rheumatism, etc.

The ferruginous waters, like the Columbian and Washington, produced remarkable effects in chlorosis and anæmia, and it was certainly astonishing that the comparatively small amount of iron which they contained should accomplish such satisfactory results. But as the iron was in combination with alkalies and carbonic acid gas it was immediately absorbed, and produced effects in the system which could not be obtained by large doses of ferruginous drugs. Some years ago the late Dr. Thomas McBride and himself undertook a series of experiments which fully demonstrated this. Two classes of subjects were selected, the first in robust health and the second suffering from well-marked anæmia, and careful records were kept of the general condition, the microscopical examination of the blood, and the sphygmographic tracing in each individual. For a certain definite period tincture of the chloride of iron was administered regularly to all the subjects, with the result of producing no effect upon the healthy subjects and only a very moderate improvement in the anæmic ones. Then the water of the Columbian Spring was substituted for this, and it produced such constant and severe headache in the healthy individuals that it soon had to be discontinued, while in the anæmic ones there resulted a much more marked improvement. With the sulphur waters of Saratoga he had never noticed any appreciable results, and the same was true of its so called alterant waters; but with the Hathorn water, given hot (and often in hot milk), especially when an iron water was used at the same time, he had seen remarkable alterant effects produced, and found the treatment very successful in scrofula, rachitis, etc.

It had often been contended that the efficiency claimed for mineral waters was generally due to the regulated diet and habits of life prescribed for patients undergoing such treatment; but he believed that while the enforced regimen undoubtedly had much to do with the beneficial results noted, the waters themselves, when given with discrimination, had a distinctly remedial effect. Such waters as the Congress, for instance, acted in the first place in a mechanical way, stimulating all the secretions of the abdominal viscera, and secondly by causing vital changes, increasing metabolism and eliminating effete material. In dyspepsia depending on gastric or intestinal catarrh, or on hepatic derangement, and in nephritis and obesity, he had some excellent results produced. The Hathorn was a stronger water, and was especially indicated in lithiasis, oxaluria, biliary concretions, and chronic fecal poisoning. In conclusion Dr. Burchard spoke of the unfortunate lack of proper bathing facilities at Saratoga, and stated that in the coming season this would be, to some extent at least, remedied.

The Limitations for Vaginal Hysterectomy in Malignant Disease of the Uterus.—The first paper of the afternoon session was one by Dr. Joseph E. Janvrin on this subject. (See page 29.)

Dr. George T. Harrison, opening the discussion, said: It scarcely admits of doubt now, in the light of the results obtained by operators, especially in Germany, that carcinoma of the uterus, which most commonly gives the indication for the performance of a kolpo-hysterectomy, may be cured, provided the operation is performed at a comparatively early period of the disease. According to recent statistics ten to fifteen per cent. remained free from a return of the disease eight or nine years after the operation. It is pertinent to ask how many of those who succumbed might have been saved if the operation had been performed in time. It is absolutely certain that a large percentage might have been permanently cured. It may be said, therefore, that the question of the curability of cancer resolves itself into an early and accurate diagnosis of the disease. A closely related question is the all-important one which Dr. Janvrin has so ably discussed in the paper he has just read, *i.e.*, the limitations of the operation. Schauta, who has lately studied this subject very thoroughly, gives what he terms a lower and an upper limit of the indications to total extirpation. The upper limit of the indication to total extirpation in carcinoma is present in every case, no matter whether carcinoma of portio, cervix, or corpus, as soon as the neoplasm is susceptible of diagnosis. The lower limit of indication of the vaginal extirpation in carcinoma, according to this authority, is present when the disease has spread into the depth of the tissues to such an extent that operation is no more practicable. Superficial spread he does not regard as contra-indicating the operation. Partial amputations are to be rejected in cases which are amenable to a radical operation. In practice the most important point to decide is, whether the pelvic connective tissue is still free. On the determination of this hinges the question of the practicability of the radical operation. And here great difficulties are often encountered. Anæsthesia under these circumstances may aid us vastly. If the uterus is freely movable, the cervix not too much enlarged, and no suspicious infiltrations are felt, the prospect of a successful issue is excellent. On the other hand, if the uterus is fixed and the parametrium is the seat of hard nodular infiltrations, a radical operative procedure is certainly contra-indicated.

According to the views of Schroeder, which were assuredly correct, a very large cervix contra-indicates the radical operation, because the extraordinary size is due not only to enlargement of the cervix, but also denotes disease of the adjacent connective tissue. It must be borne in mind, however, that a certain degree of mobility may exist in cases which do not admit of operation, for here an infiltration may exist on one side of the parametrium and the uterus may rotate around this as an axis. A certain degree of mobility may also be found in the uterus, in cases in which the carcinoma has extended to

[1] Archiv. für Gynäkologie, Bd. xxxix., Hft. 1.

the bladder or the connective tissue between bladder and uterus, and left the broad ligaments free. If mobility alone, therefore, does not indicate an operation, so, on the other hand, fixation of a greater or less degree does not necessarily contra-indicate the operative procedure under discussion. The diminished or suspended mobility may not only be caused by the extension of the carcinoma to the neighboring parts but may also be due to old inflammatory processes, especially to adhesive perimetritis. If the parametrium in the vicinity of the uterus is free and abnormal thickenings are found in the region of the tubes and ovaries, if we feel the fixed ovary in them, or if we find this condition in Douglas's cul de sac, we may safely infer that we have simply to deal with inflammatory processes. If, on the other side, a number of irregular swellings are found laterally close to the cervix, or if a number of small nodules, like a string of pearls, are found in the folds of Douglas, the dissemination of the carcinomatous process scarce admits of doubt. It deserves mention that in the determination of the question of the mobility of the uterus, the knee-chest position of the patient offers frequently great facilities.

Dr. A. J. C. Skene sent a communication in which he said that within certain limits, vaginal hysterectomy was the best operation that could be performed. (See page 30.)

Retention of Menstrual Blood in Imperfect Hymen.—Dr. J. R. Vanderveer read a paper on this subject. He related a case which was characterized by increasing dysuria, aggravated at the menstrual periods, and spoke of the importance of early recognition and prompt treatment of this condition.

Dr. Harrison said that the higher up the atresia was situated, the greater the danger in rapid evacuation. When it was high, rapid evacuation might have the effect of loosening the distended Fallopian tube from its attachments, with the result of causing it to burst, and thus give rise to peritonitis. This was doubtless the reason why this procedure was formerly considered so dangerous. In ordinary cases, however, there was no danger in rapid evacuation.

Dr. Burchard related a case in which a young woman menstruated regularly through the rectum, in consequence of the results of diphtheria when she was six years of age, which attacked the genitals and produced atresia of the vagina with ulceration, resulting in a large fistula in the recto-vaginal septum

Brown Séquard's Paralysis Resulting from Syphilis.—Dr. S. T. Armstrong read a paper on this subject, in which he reported a case of this kind, and spoke of the importance of adopting anti syphilitic treatment in doubtful cases of paraplegia.

The Latest Thing in Suicides.—Novelties in the suicide business have been plentiful enough of late. High jumps, ropes, pistols, poisons, and holes in the water will soon be out of fashion. Marguerite Borel has just introduced a new style, *fin de siècle* beyond a doubt. Her faithless lover, Paul Convert, deserted her. Marguerite didn't want to live, so she purchased in different drug stores an immense stock of leeches. Then she went home to her nice little apartments in Boulevard de la Villette, Paris, where she undressed, liberated the leeches, and applied them all over her body. In other words, she modestly made an overcoat of them. Next morning she was found still alive and taken to the Lariboisière Hospital, where she died.—*The Sun.*

Mercurials in Influenza.—In a paper on influenza read at the recent meeting of the American Medical Association, Dr. Hemenway stated that he rarely had occasion to see a patient twice if he had given a large dose of calomel at the start. This was also the experience of Dr. F. Peyre Porcher, of Charleston, who wrote in an article in this journal that he never visited a patient more than four days after having given a mercurial and rhubarb purge at the beginning, as in yellow fever.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 13, 1892.

H. P. Loomis, M.D., Vice President, in the Chair.

A New Material for Models.—Dr George C. Freeborn presented specimens illustrating their use. For purposes of instruction models are often very useful, but as usually made they only present three dimensions, length, breadth, and thickness. In many cases it is desirable to illustrate some of the physical properties of the object, *e.g.*, flexibility and elasticity, these properties being especially useful in models of some of the histological elements. With the mass to be described these two important properties have been gained.

The mass used in making these models is a mixture of glue and glycerine, or of gelatine and glycerine, the former being more economical and giving an opaque model, and the latter yielding a transparent model. The proportion of the ingredients varies according as a more or less flexible mass is wanted. A mixture of equal parts of glue or gelatine, by weight, and glycerine, makes a firm, fairly flexible mass. By increasing the quantity of glycerine to two or three parts, a less firm but more flexible and elastic mass is obtained. In the author's experience, the most useful proportions are one of glue or gelatine and two of glycerine.

In making the mass the glue or gelatine is soaked in water until it has become soft, then all the surplus water is drained off and the soft mass added to the glycerine which has been heated on a water-bath. When the glue or gelatine has become melted, the thick, tenacious mixture is strained through cheese-cloth, and again heated on the water-bath for at least an hour to drive off the water. If this is not done, the evaporation of the water, after the model is cast, causes considerable shrinkage.

Any desired color can be given the mass by adding to it, while melted, a concentrated solution in water of an aniline dye. Care must be taken not to add an excess, or it will cause staining of the hands upon handling the model.

Making the Model.—He had found paraffine the most useful material for making the model from which the plaster mould is made. Other materials, such as wood or clay, may be used, but paraffine is preferable on account of the ease with which it can be melted out of the mould without damaging it. The paraffine is cast in a block or slab, in a wooden frame placed on a smooth level surface. When cold, the wooden frame is removed, and the block is ready for shaping into the model. In casting slabs, the melted paraffine is run into tin trays of the desired size and depth.

The outline of the model to be made is drawn on thick brown paper, and cut out with a sharp knife or scissors, and is then placed on the slab of paraffine as soon as it has become solid, but while still plastic. With a thin and narrow knife blade, the edges of the paper pattern are followed around, carrying the point of the knife down to the bottom of the tray. This cuts away all the surplus paraffine, which can then be pulled out of the tray. The outline model is now allowed to become perfectly hard before it is removed from the tray. The model is next brought roughly into shape by shaving with a sharp knife, still further smoothed by gentle scraping with glass, and finally finished by rubbing with bits of cloth moistened with turpentine. The model is always made in two parts, and a mould made of each.

Making the Mould.—The model is placed on a well-oiled, smooth surface, the plane side of the model down, and a frame built around it with strips of wood. Plaster of Paris mixed into a cream with water is then poured into this frame until the highest point of the model is covered to the depth of at least an inch. After this has set, the frame is removed, and the mould stood up in a tray. The model is melted out by allowing the flame of a Bunsen burner to play against it, after which it is given three coats

of shellac varnish, each coat being allowed to dry thoroughly before applying the next.

Casting the Model.—Both halves of the mould are placed in a perfectly level position and the surfaces and depressions well oiled. Each half is now filled with the melted mass until it projects slightly above the surface of the mould, using the mass at as low a temperature as possible, in order to avoid contraction of the model on cooling. When perfectly cold, the two halves are joined in the following manner: Remove one half of the model from its mould, then paint the exposed surface of the second half, still in its mould, with some of the modelling mass at a fairly high temperature; next place the other half on it, and adjust its edges to the half contained in the mould. After two or three hours remove the complete model from the mould, cut away all rough spots at the line of junction, and finally finish by painting with a brush wet with boiling water.

All finished models should be preserved in their moulds, to avoid distortion. The mass is likely to prove useful in making casts of irregular surfaces and cavities, as on account of its flexibility it can be easily removed without damaging the object, when a plaster cast would either break the object or be broken itself. To illustrate this adaptation of the process, Dr. Freeborn exhibited a case of the base of the human skull. He also presented models of a red blood-cell, from the human subject, and also from the frog, a crenated blood cell, and several nerve cells.

Dr. H. P. Loomis asked if these models were durable, as he had seen some which had been made by a similar method, which had become very hard in the course of a year.

Dr. Freeborn replied that some of the models which he had presented had been made a much longer time, and were as soft and flexible as when first made.

Abnormal Origin of the Coronary Artery.—Dr. Warren Coleman presented two specimens of this condition. In one it was located one-half inch, and in the other one fourth of an inch, above the free margin of the semilunar valve when pressed back against the vessel. With regard to the coronary circulation, it had long been held that the semilunar valves were pressed back during systole against the orifice of the coronary artery, thus preventing the entrance of the blood into this artery; while during diastole, as a result of the elastic recoil of the aorta and the reflux of the blood, the valves were forced into position. This has usually been accepted as the explanation of the mechanism of the coronary circulation, but it was manifest from the specimens just presented, that in these cases the coronary arteries must have become filled, like the systemic arteries during the systole of the heart. In this connection it is interesting to recall some experiments made a few years ago by Dr. Newell Martin, of the Johns Hopkins University. By means of specially-devised apparatus, and the use of defibrinated blood, or normal salt solution, circulating through a mammalian heart after its removal from the animal, he had been able to prove that the systemic pulse and the coronary pulse were synchronous. Even when the coronary valves were hooked back so as to destroy their action, this synchronism was not affected. Again, it is to be remembered that in aortic stenosis, although the valves are not thrown back, the coronary circulation is fairly well maintained.

Dr. H. P. Loomis remarked that if records were kept of all these cases, he thought it would be found that this situation of the coronary arteries was not uncommon.

Occlusion of the Right Ureter—Cystic Degeneration of the Left Kidney—Abundant Excretion of Urine.—Dr. Coleman also presented a specimen of carcinoma of the uterus which had just been removed from a patient in the New York Cancer Hospital. The posterior wall of the bladder had become adherent to the uterus in such a way as to occlude the lower part of the right ureter, and as a result this ureter and the pelvis of the right kidney were greatly dilated. The left kidney had been converted into a large cyst, and yet, strangely enough, the excretion of urine, which had been quite abundant during life, must have been carried on by the remains of this kidney, as the function of the other had been entirely destroyed.

Various Congenital Malformations.—Dr. J. S. Thacher presented the body of an infant, aged eleven days, which exhibited the following malformations: A large spina bifida; a double talipes equino varus, an absence of the thumb on one hand, and apparently of the radius on this side; and a blending together of the two kidneys into one with a single ureter, and a single opening into the bladder. The child had been in the Presbyterian Hospital, and had seemed well up to a few hours before death, when it refused food and failed rapidly. As no history was obtainable, he was unable to say whether or not this large spina bifida had presented any special obstacle to delivery. On dissecting this tumor, its walls were found to consist of skin and subcutaneous tissue, and the expansions of the dura and pia mater, which were all blended together, except near the pedicle, where there was some separation of the dura and pia. The fluid contained in the meningocele amounted to 560 c.c. Nothing resembling the cauda equina was found, but the nerve fibres appeared to be spread out upon the walls of the sac.

Photo-micrographs of the Filaria Sanguinis Hominis, and of an Undescribed Colony of Bacteria.—Dr. J. M. Byron presented cases of the above. The photograph of the filaria was taken instantaneously, and was an excellent reproduction of one of the specimens recently presented to the Society. The colony represented in the second photograph was remarkable in consisting of a number of mathematically perfect concentric circles, presenting five or six different colors. Nothing more had been learned as yet of the characteristics of the undescribed bacillus which forms this peculiar colony, than that it was a bi-polar bacillus of very small dimensions.

Ganglionic Neuroma of the Supra-renal Capsules.—Dr. R. G. Freeman presented gross and microscopical specimens which had been removed from a little girl of five years, who had suddenly died after an operation on the hip-joint. At the autopsy the lungs showed a beginning broncho-pneumonia, considerable anthracosis, and one bronchial gland, which was cheesy and calcareous. The tumor, which was hard and round, and measured 2 ctm. in diameter, was situated in the left supra-renal capsule. Microscopical examination showed it to be a spindle-cell sarcoma, containing many large cells corresponding in appearance to ganglionic cells. These cells contained fairly large nuclei, and one or more well defined nucleoli.

On reviewing the literature of these tumors, he had been able to find a description of two such cases. The first was reported by Weichselbaum, and was taken from the body of a man, seventy-six years old, who died of pleurisy. The tumor was about the size of a cherry, and was designated "a ganglionic neuroma" on account of the presence of these ganglionic cells, the remainder of the tumor being considered as made up of nerve-fibres. The cells were distributed in about the same way as in the specimen just presented, they were spherical or elliptoid in shape, and the nuclei were generally eccentric. In the other recorded case, no nerve-fibres were found, but fibrous tissue, and smooth muscle tissue, and in size and shape it was not unlike a large white kidney. The specimen was found in a man, thirty years of age, who had suffered from Addison's disease, and it was described as "a ganglio-fibro myxoma."

A Case of General Tuberculosis—Death from Acute Pneumonia.—Dr. L. Emmett Holt presented the above specimens. A female child, aged three and a half years, with tuberculous antecedents, who had suffered for one year before death from tubercular glands in the neck. In the summer of 1891 she had an ordinary attack of entero colitis, after which she remained delicate, mode-

rately emaciated, and in a generally wretched condition. An examination of the chest in the middle of September showed only coarse scattered râles. There were occasional attacks of intestinal trouble during the fall, but no blood appeared in the stools. During October there was considerable improvement in the general condition, and she gained in weight. During November, however, she failed visibly and became exceedingly irritable if disturbed, but dull and apathetic if left to herself. Photophobia was quite marked; in fact, from her previous history, it seemed highly probable that a tubercular meningitis might be developing. A record of the temperature was kept, but no rise occurred until near the end of November; it then ranged between 100° and 103° F., continuously for one month. A few more râles were found in the chest, but no increase in the nervous symptoms. Eleven days before death the temperature suddenly rose to 104° F., and during the remainder of the disease it fluctuated irregularly between 101° and 104.5° F. With this high temperature there was an increase in all the pulmonary symptoms—cough, prostration, dyspnœa, etc. Signs of complete consolidation of left lower lobe soon appeared, and a little later similar signs over the right base behind. She died of exhaustion.

At the autopsy, the brain was found perfectly healthy. The bronchial glands were greatly enlarged, especially on the right side, where they formed a mass of some size about the right bronchus, one and a half inch in diameter and three quarters of an inch thick. These glands were cheesy, but not suppurating. In the upper lobe of the right lung there were scattered nodules of tubercular pneumonia from one-eighth of an inch to half an inch in diameter, cheesy at the centre, the intervening pulmonary tissue being quite healthy. At the anterior border of the right middle lobe the oldest process was located. On section, this portion showed fibrous tissue surrounded by old cheesy masses, and here the lung was adherent to the pericardium. The lower left lobe was uniformly consolidated, of a reddish-brown color, with a thin layer of recent lymph on its surface. In the upper lobe of the left lung a circumscribed nodule of pneumonia was found, about one and a half inch in diameter, of a brownish-red color. On section, the rest of the lobe was found to be healthy. The lower lobe was uniformly consolidated, of a grayish-red color, slightly mottled, and showing a very slight pleurisy on its surface. The microscopical examination of the lungs showed a process having some of the characters both of a lobar pneumonia and of a bronchopneumonia, but not quite those of either. There was not much fibrin in the alveolar exudate, but the pus and epithelial cells were very numerous. The spleen, liver, and kidneys showed no essential changes. The small intestine was healthy throughout. The colon showed about a dozen old ulcers, chiefly in the rectum and descending colon, the largest ones being over an inch in diameter. The mesenteric glands were all enlarged and cheesy.

Pleuro-pneumonia; Empyema; Operation; Death from Secondary Pneumonia in the Opposite Lung.—Dr. Holt also presented specimens of the above. A female child, two years of age, was taken with symptoms of influenza, which rapidly developed into pneumonia. On the fourth day, signs of consolidation were found at the right base posteriorly. The temperature ranged between 101° and 104° F. for ten days; it then fell nearly to normal, but there was no improvement in the general symptoms. Examination of the chest showed at this time exaggerated breathing on the left side, and over the whole right chest there was dulness almost amounting to flatness, excepting at the extreme apex in front, which was tympanitic. There was distant bronchial breathing everywhere, but no râles, although two days before râles had been numerous. The heart was displaced to the left, beyond the nipple line, and an exploratory puncture showed pus. Two days after, the chest was incised in the eighth intercostal space, at the posterior axillary line, and half a pint of pus evacuated, and drainage-tube inserted. For three days after the operation the child did well, the temperature remaining below 101° F.; it then rose rapidly to 104° F., and fluctuated between 103° and 105° F. for five days, at the end of which time the child died, on the twenty first day of the illness.

The autopsy showed all the organs excepting the lungs essentially normal. Over the right side of the chest there were recent adhesions at the apex anteriorly, to the pericardium and to the diaphragm; posteriorly, the lung was not adherent. There was a large quantity of pus in the pleural cavity. The right lung was covered everywhere with a thick layer of yellowish-green fibrin. The lung was moderately compressed, but nearly as large as the left one. On section, it showed consolidation everywhere except along the anterior border. The left lung showed recent fibrin over the lower lobe, which was about three-fourths solidified; elsewhere, slightly emphysematous. Section showed a typical broncho-pneumonia. The bronchial glands were enlarged but not cheesy. The cause of death in this case seems to have been the development of the disease in the left lung, which was apparently coincident with the rise of the temperature three days before death. The rapidity of the formation of the pus was very striking. A bacteriological examination was made from the pus drawn from the chest at the exploratory puncture, and pure cultures of the pneumococcus obtained.

Compression Myelitis, Associated with a Columnar Area of Necrosis, Extending a Considerable Distance above the Compressed Portion of the Cord.—Dr. Ira Van Gieson presented microscopical specimens from the above case. The clinical history was unfortunately very defective. The patient was a middle-aged man, who had been run over by an ice-cart, sustaining a fracture in the lower dorsal region. He survived the accident two and a half months. During this time there was an extreme degree of paraplegia, and very extensive trophic changes, giving rise to enormous bed-sores. One of these sores extended from the sacrum upward between the scapulæ, while there were ulcers over the heels, and very deep ones extending even between the calf muscles.

At the autopsy nothing was found worthy of note except the condition of the spinal cord. This was so greatly flattened in the eighth or ninth dorsal segment, as to measure only 3 by 6 millimetres. Above this flattened portion, in the dorsal region, and in the seventh cervical segment, was a columnar area of softening, situated in the posterior columns, and involving the caput of the right posterior horn. On cutting the cord transversely, the softened material flowed out, leaving a sharply-rimmed cavity. Microscopical examination of the flattened portion showed that the cord had degenerated into a fluid mass, contained within the membranes. The columnar area of necrosis was readily seen with a low magnifying power.

Dr. Van Gieson referred to a similar case which had been reported by Dr. C. L. Dana, and exhibited the plates illustrating this case. He reported his case because, with one exception, it appeared to be unique, and because he was unable to understand the nature of this process.

The Society then went into executive session.

Stated Meeting, January 27, 1892.

H. P. Loomis, M.D., President, in the Chair.

Lesions of Bright's Disease.—Dr. Francis Delafield exhibited on a screen a series of photo-micrographs showing the lesions of Bright's disease. He said that he had found it convenient to divide Bright's disease as follows: Acute and chronic congestion, acute and chronic degeneration, acute exudative nephritis, acute diffuse nephritis, chronic nephritis with exudation, and chronic nephritis without exudation. He first exhibited photographs of the normal kidney as a standard of comparison,

and then a fine series illustrating the lesions found in the various forms of Bright's disease just enumerated.

At the conclusion of this exhibition, the Society passed a vote of thanks to Dr. Delafield.

Dr. J. West Roosevelt said he wished to direct attention to the fact that Dr. Delafield had made a practical classification of the diseases of the kidneys, which was not only pathologically complete, but, in his opinion, had never been surpassed, as a guide to the clinician in diagnosis, prognosis, and treatment.

Rupture of the Lung Following Pleurisy with Effusion.—Dr John S. Ely presented a specimen from this case. The patient was a man of intemperate habits, with chronic Bright's disease, who had been admitted to Bellevue Hospital on account of pleurisy with effusion. About fourteen ounces of bloody serum were withdrawn with the aspirator, but the physical signs indicated that the chest contained a much larger quantity of fluid than this, the removal of which was probably prevented by sacculation. Shortly after admission, after sitting up in bed, he suddenly became deeply cyanosed and fell backward, and at the same time a considerable quantity of fluid was ejected from his nose and mouth. He died almost immediately. At the autopsy, the right pleural cavity was found to contain a large quantity of fluid; the lung was compressed against the vertebral column, and many adhesions caused sacculation of this fluid. At the base of this lung there was one adhesion which bound the lung quite firmly to the diaphragm, and after removing the lung and inflating it under water, two ruptures of the lung were discovered in the immediate neighborhood of this adhesion, one, three-quarters, and the other, one-eighth of an inch in diameter.

It had been suggested that these ruptures had been produced by the aspirating needle, but this could be excluded, as the rupture was on the under side of the lung, near the vertebral column, and hence out of the reach of the needle. Furthermore, the patient died very suddenly more than thirty hours after the introduction of the needle.

Gangrene of the Lung Complicating Pneumonia.—Dr. Ely also presented a specimen of the above. The patient was at first admitted to the hospital as a case of acute alcoholism, but he soon gave evidences of pulmonary consolidation, and the profuse fetid expectoration led to the supposition that there was gangrene of the lung. At the autopsy, one lung was found to be closely adherent to the thoracic wall, and the entire lower lobe was passing from the stage of red to that of gray hepatization. The base of the lung was honeycombed with numerous cavities, which were filled with fetid greenish material. It was interesting to note that these cavities all possessed a line of demarcation, or a sort of pyogenic membrane, which might in time have led to an isolation of these areas, and possibly, to a cure. The gangrene was most noticeable at the lower and poster or portion of the lung, and this situation seemed to favor the theory of gangrene complicating pneumonia, being due to stasis of the blood resulting in necrosis. There was no evidence of thrombosis.

Dr. Warren Coleman narrated the history of a case of gangrene of the lung, occurring in a longshoreman, who had fallen from a height of fourteen feet upon a log. The man continued at his work after the accident for four or five days, and was then seized with severe dyspnœa. He was taken to Bellevue Hospital, where he died about fourteen hours after his admission. The autopsy showed the chest cavity filled with sanious fluid, which had become purulent during the last twenty-four hours of life. The lung was compressed against the spinal column, it was almost completely atelectatic, and was gangrenous in that part of the lung corresponding to that part of the chest which had been struck in his fall. The exterior of the chest showed no lesion at this point, the ribs were not fractured, and the costal pleura was intact. Apparently a pulmonary apoplexy had occurred at the site of the injury, and in the subsequent breaking down had caused the rupture of a bronchus through the pulmonary pleura, for here an opening about the size of a quill was discovered, and on making pressure, gangrenous matter oozed through it. He thought the pyo-pneumothorax developed at the time of the sudden appearance of the dyspnœa.

Pure Cultures of the Lepra Bacillus.—Dr. J. M. Byron exhibited specimens of the above. These were of peculiar interest, as there had been much doubt as to the existence of pure cultures of this bacillus. The specimens presented represented the fourth generation, and they were made on agar, with glycerine containing one-half per cent. of rock candy, or two per cent. of ordinary sugar. They were obtained about eight months ago, from a patient in Charity Hospital. As a means of comparison, he also exhibited tubercle bacilli in the same culture medium. The gray cultures of the lepra bacillus appear at first as very small, star-like, grayish-white spots, so flat and transparent as to be seen with difficulty. At the end of three days they reach the size of the head of a small pin, and then apparently cease growing; but if cultivated for two or three months in the incubator, they will be found to be slightly larger, appearing as irregular granular masses, dark in the centre, yellowish at the periphery, with wavy edges. Under the microscope they bear a close resemblance to tubercle bacilli, except that some of them present a club shaped extremity, probably due to early involution forms of bacteria, on account of the necessarily prolonged cultivation in the incubator.

An Improved Turn-table for Rapidly Collecting Sediments from Fluids.—Dr. George C. Freeborn said that last November he had presented, in a crude form, an apparatus for this purpose. With it, a speed of nine hundred revolutions could be obtained, but the machine in its improved form was capable of making twelve hundred to fifteen hundred revolutions per minute, thus securing more thorough sedimentation. This machine is made by the New York Pattern Machine and Die Co.

A Lithopedion.—Dr. Wilson, of Brooklyn, presented a lithopedion. So far as he knew, no specimen of this kind had been exhibited in New York since 1865, when one was presented to this Society. The present specimen was removed from a woman, sixty-six years of age, who died in St. Catharine's Hospital, in uræmic coma, forty-eight hours after her admission. After her death, her friends stated that about thirty years before, while she was in Bavaria, her native country, she was seized with labor pains which lasted several days, and finally disappeared. She was not delivered of a child, however, although her physician assured her that she was pregnant. The child was never born, and she become the object of much ridicule from her female friends. At the autopsy, the uterus and right ovary were found to be normal, but the left ovary was the seat of a dermoid cyst about as large as an orange, consisting of a nodular shell, containing fatty material and a small quantity of hair. Situated free in the abdominal cavity, outside of and above the uterus, and in the median line, was an oblong tumor about twelve inches in length. Its long axis was transverse to the abdominal cavity, and the tumor was adherent to the anterior abdominal wall, above the umbilicus, by a small calcific plate about one inch in diameter. The tumor had no connection with the uterus or ovaries. After enucleating it, it was found to be a fœtus in a state of complete calcification. The head could be seen flexed upon the thorax, and the thighs on the abdomen; the left leg was dislocated at the knee-joint, and attached to the mass by a fibrous band; the right shoulder was quite prominent, and the digits on the hands and feet could be plainly seen. The umbilical cord could also be made out. The speaker said that he had not cut into the tumor, but judging from the weight of the mass, and its yielding to pressure, he thought it probably consisted of nothing but adipocere. In one re-

ported case, he believed even the striations of the muscles had been preserved, but in the majority of instances the interior of the mass was converted into adipocere.

THE CAVENDISH LECTURE—SOME POINTS IN THE ETIOLOGY OF TYPHOID FEVER—MR ALLINSON AND THE GENERAL MEDICAL COUNCIL—THE ASSOCIATION OF MEMBERS OF THE ROYAL COLLEGE OF SURGEONS—THE MIDWIVES' BILL—INCREASE OF SMALL-POX.

LONDON, June 11, 1892.

IN the Cavendish Lecture, recently delivered before the West London Medico-Chirurgical Society, Sir Charles Cameron (ex-President of the Royal College of Surgeons of Ireland) discussed some points in the etiology of typhoid fever. He said that the question as to whether an attack of typhoid fever could occur without an antecedent one was a question which had been discussed frequently; it had been answered in the affirmative by one of the greatest authorities on the subject, the late Dr. Murchison. The spontaneous origin of the *materies morbi* of the disease by the decomposition of fecal matters was a theory which recent bacteriological research had completely exploded. There was now a consensus of medical opinion in favor of the microbial origin of typhoid fever, and the biology of the microbe thus came to be a subject of great interest. There were pathogenic microbes which apparently soon perished when detached from the animals in which they had been developed, while others were more persistent, and the spores of many kinds long retained, like vegetable seeds, their vitality and power to develop under favorable conditions. The pathogenic microbes seemed to live and multiply when supplied with nutrient material, from which we might infer that they might, when detached from animals, become deposited by accident in dead organic matter capable of affording nourishment to them. Probably the majority of such organisms would soon perish if the animals with which they were associated ceased to exist, but it was certain that the microbes which produced some diseases would continue. For example, the bacillus malariæ and amœboid bodies, and no doubt the bacilli and other micro-organisms producing all kinds of intermittent fevers, had an independent existence. They were found in many soils—in rich alluvium, and in the holders and banks of rivers, especially in tropical and subtropical climates. They existed abundantly in the British Isles in former times, and had been got rid of by the drainage and cultivation of the soil. These organisms were clearly of the earth, but they produced specific diseases in man.

The lecturer said he was disposed to think, without admitting or denying the theory, that there was a kind of hybrid fever (typho-malarial) intermediate between typhoid fever and ague—that there were several points of resemblance between typhoid and the intermittent fevers. Dr. Harley had pointed out the intimate connection between them in the Lumleian Lectures for 1889. Dr. Johnston, in treating of the continued fevers of the Southern States of America, stated that typhoid was probably changing its character there and becoming less defined and of a milder type; he believed that many cases of so-called malaria were really typhoid fever, and concluded by acknowledging the existence of a typho malarial fever.

Sir Charles Cameron said he was inclined to look favorably on Dr. Woodhead's theory, that all bacilli were primarily saprophytes (*i.e.*, that they had an independent existence apart from animals), and that they became under altered conditions pathogenic and preyed upon living tissues. The saprophytes were, with perhaps the exception of the micro organisms connected with malarial diseases, innocuous, but, under certain conditions at present not well understood, they might acquire virulence.

MM. A. Rodet and G. Roux had stated positively that the typhoid bacillus of Eberth was merely an altered and virulent form of the bacillus coli communis described by Escherech. Their researches seemed also to show that the bacillus coli communis, which might exist in the human organism without doing injury to the latter, could become highly virulent and infective when introduced into water. They hence concluded that not only typhoid dejections, but simple fecal pollution of water, might produce typhoid fever in those who drank it. This view seemed to favor Murchison's pythogenic theory, but they really differed completely. In the latter it was assumed that the toxic principle of typhoid fever might originate in decomposing fecal matter, but, according to Rodet and Roux, a harmless saprophytic organism acquired by mere contact with water new and infective properties. It was not improbable, then, that an organism which could exist for at least some weeks in earth and water was the *materies morbi* of typhoid fever. This organism might be harmless until it had undergone certain transformations in the system, or it might be immediately infective. Such an organism was clearly much nearer akin to the microbes of malarial disease than to those of such affections as gonorrhœa, typhus fever, or measles. The conditions of soils or water had little relevancy to these, and most other of the infective diseases; but it had a great deal to do with remittent, intermittent, and typhoid fevers; perhaps, also, with dysentery and diphtheria.

The lecturer then discussed Pettenkofer's theory on the relation between ground water and typhoid, and remarked that it had not received much support in England.

After reviewing the sanitary arrangements of Dublin, the lecturer said we must look in the soil for the cause of the endemicity of typhoid fever in Dublin and in other places. That typhoid fever more than held its own could only be accounted for by assuming that the microbes of the disease had established themselves in the soil, that they multiplied therein, and that they issued occasionally from it into the atmosphere, which, consequently, became infected. This theory was greatly strengthened by the fact that the porous soils were to a much greater extent likely to be the habitat of the disease than the stiff clays. The action of strong winds and the rising and sinking of underground water more readily caused movements of air in gravels and loose soils than in clay; the escape of microbes from the former under such circumstances must the more freely occur. Hoffman had pointed out that there was in porous soils what he termed a superficial zone of evaporation in which the moisture varied from saturation to zero. If the typhoid bacillus existed in this zone it must be immersed in water and in air alternately In the former case it remained in the soil, in the latter it might be transported to the air by air-currents. The chances of detaching micro-organisms from most surfaces were slight, but it must occur now and again. Those of typhoid fever had not yet been detected in the atmosphere, but pus organisms and the microbes of diphtheria had.

The lecturer concluded by speaking of prevention. He said that all measures to be used for this end related to the ground—directly or indirectly. A supply of pure water was absolutely necessary. He said also that he was convinced that typhoid fever often occurred through underground air entering our dwellings. This might, to a great extent, be prevented by having even the thinnest layer of asphalt or allied material covering the whole of the site on which the house rested; no air or moisture could pass through such a layer. As microbes were most abundant in the upper layers of soil, the water from superficial wells should not be drank.

The most notable incident at the recent session of the General Medical Council was the removal of Mr. T. R. Allinson from the register on the ground of conduct "in-

famous in a professional respect." Mr. Allinson is a disbeliever in the efficacy of vaccination, and has written on the subject in rather free terms He also has but little faith in drugs, and terms his medical brethren "professional poisoners." The alleged misconduct for which he has been haled before the Council, however, has been his system of advertising himself in the lay press, and his giving medical advice in the columns of a weekly newspaper. If the Council are going to put down medical advertising they will have their hands full, for numbers of medical men advertise in various ways, though perhaps not to so glaring an extent as Mr. Allinson has done. What else than an advertisement is it to procure the insertion in the column of fashionable intelligence in the daily papers the announcement that "Dr. and Mrs. —— have returned to —— from ——." Where is the line to be drawn as to what is professional and what is not? In the Publishers' Column in *The Times* advertisements of medical books by leading medical men appear, but for the same books to be advertised in the ordinary columns of the same paper is *infra dig.* Mr. Allinson's proceedings have undoubtedly not been such as to commend themselves to those who desire to uphold the honor and dignity of the profession, but whether the General Medical Council will succeed in effacing him remains to be seen, for he has obtained an injunction against them in the Queen's Bench. Even if he is removed from the register the present state of the law is such that there is nothing to prevent him from continuing to practise provided that he does not assume medical titles or pretend that he is a medical man.

The Association of Members of the Royal College of Surgeons has fallen upon evil days. They were unsuccessful in the recent litigation and are now mulcted in heavy costs which they are unable to pay. At the present moment they are further suffering from internal dissensions. Meanwhile the original controversy seems as far as ever from settlement.

The Committee of the House of Commons on the Midwives' Registration bill will issue a report on the subject shortly.

Small pox is still on the increase in London.

DELIRIUM TREMENS; HAS IT A DUAL CAUSE? "NO."

To the Editor of the Medical Record.

Sir: When a physician is writing on a subject so familiar to the profession as the one in question, it would savor too much of the pedant for him to take up time in describing its symptoms and course. Keeping that principle in view, I shall at once enter on the question raised above.

Text-books tell us that an attack of delirium tremens is due to one of two causes, viz., drinking to excess, and here it occurs at the height of a debauch, or the sudden deprivation of alcoholic stimulants from a person, or system, habituated to large and repeated doses. These are the causes accepted by most authorities. We find, however, as related by Hammond, that eminent physicians have questioned both of the causes above stated. "Thus," he says, "Aitkin denies, in very positive terms, that delirium tremens may occur as a consequence of cessation from drinking." "While Watson, on the other hand," continues Hammond, "assigns no other cause than that the habitual stimulus has been diminished or abandoned. We thus see, strange as it may appear, that both the causes now accepted have been in the past discredited by different observers.

Now, it is certainly time to look the question squarely in the face and endeavor to determine (1), whether there is a dual causation, and (2), if not, what has been the stumbling-block in arriving at the truth of the matter. In looking at the matter from the above position, the question arises, Have we, in the whole realm of medicine, any analogy for the dual causation of delirium tremens? and to that question I must answer with an emphatic "No." To me, it is unreasonable to believe that similar conditions can be induced by causes of an opposite nature, or that delirium tremens can be caused both by an *excess of alcohol on the system*, and the *cutting off from the system* of that very stimulant. But, at the same time, in coming to that conclusion I feel assured that medical authorities must have strong apparent data on which to base their opinions. Apart, however, from those grounds, there is another influence at work to bias that opinion, which is, copying ideas in successive text books. I believe that in this way, to a great degree, is due the propagation of the error that delirium tremens has a dual causation. Before, however, I enter further into the question let me relate two cases of delirium tremens which have, among others, occurred in my practice within the past few years.

About three years ago I was summoned to W. G——, a daily drinker, suffering from a very tight stricture. As he was averse to a cutting operation I advised his removal to a vacant house near my residence, for the purpose of treating by continuous dilatation. As he was very frightened at his condition he at once concurred in all my suggestions. I put him to bed for a week, and during the following fortnight allowed him to move around a little. During the treatment I allowed him a full milk diet, and at no time was he unable to sleep. At the expiration of the three weeks of treatment I allowed him to return to work. (As his work was in a seaport village, and he still retained the house near me, he had to go and come daily a distance of seven miles each way.) He continued his work in that way for a week, when he contracted a fever. The fever I treated in my customary way—putting him to bed and cutting down his nourishment to almost nil On the third day his temperature dropped to normal, but that night he got no sleep. Next day he developed marked symptoms of delirium tremens, the family was alarmed, and I nonplussed. Not knowing his habits, my previous treatment of him for three weeks, when nothing of the nature occurred, put me off the scent. In relating the case, however, to a *confrère*, he remarked, Do you know that he (the patient) is a hard drinker? This cleared up the case and taught me a lesson, viz., that even a daily and hard drinker may stop the habit with impunity, provided his digestion be good and he take plenty of nourishing food. I am sure that my patient took no alcohol during the first three weeks of treatment, as he was cared for by his wife during the whole time, who is bitterly opposed to the habit. He probably returned to his habit during the week at work, to again relinquish it when I put him to bed and cut down his nourishment; this time, however, he developed delirium tremens as a result of being deprived of both food and alcohol.

The next case is still more interesting, teaching, too, another lesson. About eighteen months ago I was called to see a retired planter suffering from tropical lymphangitis. The attack was a severe one, and, as is frequently the case, the stomach was implicated, so that there was incessant vomiting. He had had the attack for two or three days previous to my being called, and although I was able at once to control the retching, yet for the next two days he was unable to retain anything on his stomach, and to make matters worse he had a little diarrhœa, preventing a resort to nutrient enemata. On the morning of the fifth day of attack, on visiting, his wife gave me the information that he had been unable to sleep the previous night, and that he seemed to be going out of his mind. On going into his room I found him in a state that appeared to be delirium tremens. Questioning his wife as to his habits she informed me that he only bought four ounces of rum per day, of a cheap, hence watered, kind, and that this amount he shared with an aged relative in the house. This story caused me to hesitate in pronouncing his condition delirium tremens. Next day,

finding the case more pronounced, I again taxed his wife about his habits, when she reiterated her former statement, adding however, "but he has done that for a long time—probably twenty years or more." This addition to her story led me to conclude that it was not so much the quantity, but the fact that he had indulged in the habit for so long a time that had resulted in delirium tremens, when he was thus unable to continue it; and treating him in accord with that conclusion—he could now retain a little milk and brandy—he was soon over his trouble. Two years previously he had had a similar attack, when his physician, one of the oldest and most prominent on the island, failing to diagnose the complication, pronounced that he would die, and that nothing could save him. His recovery in that instance I attribute to one or both of two causes, either that his physician's last prescription contained sufficient alcohol to relieve him, or that his stomach, gradually improving, enabled him to take nourishment.

This case is remarkable, illustrating as it does, that not only is the hard drinker liable to delirium tremens from failing to use his accustomed stimulant, but that also the moderate drinker may develop it, under certain circumstances.

The cases above mentioned also serve to prove unmistakably, that about one of the alleged causes of delirium tremens there can be no doubt whatever, viz., that delirium tremens can be induced by withholding the accustomed stimulant from a person addicted to the habit of taking it regularly

Granting, then, that we have proved one of the two alleged causes of delirium tremens, let us now consider the second, viz., that delirium tremens can be induced by the presence of too much alcohol in the system. Now, I do not deny that we may have alcoholic poisoning, with perhaps delirium therefrom, but I do maintain that the result is in no way similar to that produced by the withdrawal of alcohol from a system accustomed to it. In order to maintain my position, I shall relate a circumstance which occurred on the day I began to write this paper, as it serves to illustrate well how delirium tremens occurs in those who apparently drink themselves into it. On the day in question a man came into my office whom I knew to be a hard drinker at times. Knowing that I could take the liberty, I asked him whether he had ever seen a man in delirium tremens, thinking perhaps that he would give me his experience. He replied, "Oh, yes, and I confess I was so once myself." "Let me hear how it occurred," I said. "I was at that time," he answered, "keeping a liquor-shop, and I made it a habit to take a bitter the first thing as I opened in the morning, and some eight or ten at intervals during the day. This I had done for months. But one morning, as I took my accustomed drink, it immediately returned, and I took another and another with the same result. Thirst now came on and I drank enormous quantities of water, but only to vomit it as soon as it hit my stomach. I now tried stimulants in various forms, only, however, to be instantly rejected by the stomach; and by night I was in delirium tremens, and fortunately I have a little medical knowledge, as you know,"—he was once in my employ—"which enabled me to check it before I got completely off my legs."

Now, this man's story, thus told, illustrates well, as I have said, how delirium tremens occurs in those who apparently drink themselves into it. It will be found in all such cases that the stomach has absolutely refused to retain anything for at least twelve hours. Now, in debauches that result in delirium tremens it is customary to drink from twelve to twenty or more times, in the twenty-four hours; hence, when the stomach refuses to retain anything for even six hours, the patient has been cut off really from six to eight or ten drinks. In the case of the man above mentioned delirium tremens set in in twelve hours, because his system had been deprived actually of from eight to ten drinks. It will be found, too, that in debauches extending over a day or two or more, the habit of drinking very frequently can be formed in a very short time; and it may be laid down that the shorter the interval between drinks the earlier will delirium tremens commence after the stomach has refused to do its office, and that for obvious reasons.

Now, most authorities state that nausea, vomiting, anæmia and other gastric disturbances are the earliest symptoms of delirium tremens. What I maintain, however, is that it is due to those symptoms appearing in a drunkard that he gets delirium tremens; for, in the first place, the patient is unable thereby to take the proper amount of nourishment, and in the next, as those symptoms increase, he is cut off from even his customary stimulant. It is true the gastric disturbances above mentioned are caused by his indulgence in alcohol, but such by right belong to the chronic effects of alcohol. It is thus seen that when the chronic effects reach that stage which cuts off the further indulgence that delirium tremens results, but we must remember that that result is not due to the accumulation of alcohol in the system, but to the fact that the habit is thereby stopped, and that in the vast majority as effectually and with the same results as if the patient of his own will had relinquished the habit. I have thus endeavored to make plain to my readers that delirium tremens occurs, not from a dual causation, but from one causation, and that is the cutting off of the stimulant either voluntarily or involuntarily from a person previously habituated thereto. This may, I think, be enlarged as follows:

Delirium tremens is a disease of the nervous system, characterized by various mental disturbances and brought on in a person habituated to alcoholic stimulants, when the supply of stimulant has been stopped, either voluntarily or involuntarily, and when at the same time the full supply of food necessary for the maintenance of the system in health has been cut off, either voluntarily or from inability of the stomach to retain and assimilate such.

Perhaps I should make it plain that I did not quote the cases above mentioned for the sole purpose of bearing out my contention, but from the fact that each presents peculiar features.

Now, although I have myself answered the question involved in the title of this article, I now put the question for a discussion to the many readers of the RECORD, with the assurance that I could find no fitter tribunal. I must ask them, however, to depend not so much on their past experience as on the careful investigation of all fresh cases that present themselves. And I feel assured that you, Mr. Editor, will give your pages for the elucidation of a question which even if of minor importance is yet worthy of investigation for the sake of the truth involved.

R. F. LICORISH, M.D.

BRIDGETOWN, BARBADOS, WEST INDIES, May 28, 1892.

Fighting Mice with a Bacillus.—Professor Loeffler's bacillary crusade against the field-mice of the Thessalian plain has ended in victory. The latest reports announce that the fields are strewn with the corpses of mice. It will be remembered that Professor Loeffler some time ago discovered a new bacillus, the "bacillus typhi murium," which has the power of producing a certain disease in mice, and in mice alone. A plague of field-mice, threatening to destroy the harvest, having appeared in Thessaly, he was appealed to by the Greek Government, and immediately started for Athens. He began his experiments by treating field mice in the laboratory with injections of his bacillus cultivation, and when these experiments showed his method to be undoubtedly the right one, he started for Thessaly with a staff of Greek doctors. Bread-crumbs, saturated with the bacillary substance, were strewn broadcast over certain fields, and as early as a week later the results were visible. Success being now assured, Professor Loeffler will return to Germary, and the bacillus cultivation will be carried on at the seat of war itself.

AN UNIQUE DERANGEMENT OF THE KNEE-JOINT DEMANDING SURGICAL INTERFERENCE.[1]

BY ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, ETC.

THE phrase internal derangements of the knee joint, given by the English surgeon Hey, it is now well understood comprises sundry disorders which are more definitely known and expressed as floating cartilages and as displacements and distortions of the intra-articular cartilages. But while the ordinary conditions belonging to loose bodies in the knee joint are tolerably clearly understood in their etiology, yet sundry peculiarities belonging to this affection have only been recently brought to notice. I have had occasion elsewhere [2] to report two cases of what was then considered, upon microscopical examination, to be sarcomatous pedunculated growths of the knee-joint, but in which the progress of time, as well as an increase of experience, has shown that they were more largely due to inflammatory changes, rather than to those of neoplastic origin. These floating bodies, which present the symptoms of the usual loose cartilage, are, thanks to the able investigations of Mr. Herbert Allingham,[3] to be attributed to outgrowths from the alar ligaments, fatty in character, and somewhat changed in character by the repeated traumatisms from being nipped between the opposing ends of the bones. Since the report that I then made of my cases I have had an additional experience in which this demonstration of the origin of such fatty growth was positively made out.

Within the past two years however, another condition producing impairment of this articulation has come, in two instances, to my notice, and concerning which I have been unable to find any help in the literature upon the subject of joint affections. The first case was as follows:

CASE I.—A lady, forty-five years of age, married, in good general health, and free from rheumatic affections of any marked character, placed herself under my charge in January, 1890, for the treatment of a subacute synovitis of the left knee-joint. There was but a moderate effusion, and this had existed but a short time. Her joint trouble, she said, had been produced by much walking on the polished floors of a new country house. Only afterward, by much cross-questioning, did I learn that in the spring of the year 1889, she had, by the falling of her horse while driving, been thrown against the dashboard of the vehicle, striking with considerable force upon her knees. This injury, however, produced no lasting effects, and did not cause even any ecchymosis of the skin. Following this very slight traumatism she complained all the ensuing summer and fall, of stiffness in both knees, and more particularly on the left side. This symptom was noticed more especially after sitting still a length of time. The synovial effusion for which I was called upon to treat disappeared under the use of a light Pacquelin cauterization and subsequent fixation of movement by a water-glass splint. It recurred again, after considerable exercise, within the next three months.

I saw the patient again April 1, 1891. She complained much of a tight band around the knee above the patella, and that the knee-joint movements were further impaired in their action. For some time past increasing grating and rubbing sensations in the joint were noticed, and complaints were made of tripping, from time to time, over the slightest inequalities of the carpet in the room. As nothing definite was revealed by my examination, it was supposed that the slight stiffness observed, and the limitation in the motion of the joint, were due to the previous inflammatory action. She was, accordingly, directed to persevere in walking, at first with crutches and then with the cane, and to resort to massage. I did not see her again until my return to New York in November, 1890, from my summer vacation. She had been out of town and progressed only moderately well during the summer. She now called attention to a peculiar jumping movement, which could only be felt when the fingers resting lightly upon the patella, the leg was carried forward in extension, but could also be seen just outside the middle of the patella when flexion was partially accomplished, or more exactly, when the limb was bent one-third toward a right angle. With this jumping or overriding there was increased inability to flex the limb after it had been brought into a fully extended position, and, indeed, she stated that she could not change her limb from this extreme straight position to a flexed one unless, first, the limb was allowed to rest upon the floor. If the limb was kept rigidly extended in mid air, she would be unable to flex it without great pain, and if, while thus elevated, I forced the flexion, great pain was experienced, and with a jumping sensation, felt best to the outer side of the patella, the resistance would be overcome. There was also, with this, considerable difficulty when the limb was flexed, in bringing it to the position of extreme extension, though much less so than in the reversed conditions. The limb above the knee was atrophied, but not more than is usual in arthritic troubles. On testing it with a leg dynamometer, the left extensor femoris muscle was found to be one-third weaker than the corresponding muscle on the right side. Its tone was, however, markedly improved under the use of galvanism, without improvement in the mobility and satisfactory working of the knee joint. There was, therefore, no ground to believe that any paralysis of this muscle, which had been suggested as a cause, existed to explain the condition. I was also able, when the limb was fully extended, the heel supported, and the quadriceps extensor was thus fully relaxed, to appreciate, by crowding the patella against the femur or by gently pushing the patella upward, that a sudden overriding from the interposition of some abnormal membrane or tissue existed. This corresponded to the jumping sensation previously alluded to upward. As this was above the line of the joint, the possibility of a slipping of the semilunar cartilage, which the location of the slipping sensation outside the patella first originated, was excluded. None of these conditions was to be found in the right knee. No effusion was now present, nor thickening of the joint.

The diagnosis arrived at was not satisfactory, but it was believed that possibly a fatty growth from the lengthened alar ligament or from a portion of the subpatellar fat herniated into the joint, or even possibly some unusual form of distortion of the external semilunar cartilage existed, and an exploratory incision was therefore suggested to the patient. This she was unwilling to

[3] Internal Derangements of the Knee-joint, 1889.

accept, and it was only after the persistence of her symptoms till April 1, 1891, that she consented to the proposed surgical measure. At that time she was considerably disabled, walking with much limping and stiffness, and with the continuation of the difficulty of bringing the foot forcibly forward in walking, and of unlocking the limb when fully straightened out.

After appreciating the risk of failure from the admitted obscurity of the affection, and also the stiffness that might follow the operation, it was performed under ether and full antiseptic precautions as follows: By an incision three and a half inches long, beginning at the top of, and three-quarters of an inch to the outer side of the patella, and running downward, the fascia and capsule were separately incised, exposing the synovial membrane first at the upper inch of the wound. This membrane was here then divided, and this opening into the joint eventually enlarged downward to the cushion of the subpatellar fat, making the opening in the joint in length nearly two inches. This allowed of the satisfactory exploration of its cavity by the finger being introduced through the opening with the limb extended. Afterward by flexing the limb and rotating it as much as possible, the intra-articular cartilages were felt to be firmly attached and without any distortion. Now, by raising the patella, at first by hooks at its cut edge, but external to the synovial

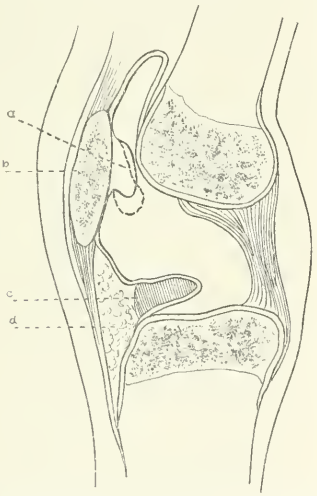

FIG. 1.—(Altered from Alliaghan's "Derangements of the Knee-joint.") The dotted line represents the shape of the thickened synovial fold when the patella rested against the femur—the natural position. The mass appeared thicker when the patella was lifted by retractors. *a*, hypertrophied synovial fold becoming pedunculated; *b*, patella; *c*, semilunar cartilage; *d*, subligamentous fat.

membrane, and subsequently by a blunt, flat retractor passed within the joint, the patella was so much raised that its inferior surface could be plainly and entirely seen. From its surface, at about the junction of its upper and middle third, was observed a bluish-white duplicature which hung downward when the bone was thus lifted up, and which, when the retractors were withdrawn and the joint permitted to resume its natural relations, could be seen through the incision to rest between the patella and the articular surface of the femur, with its thicker free edge downward, and of a length of nearly half an inch, so that it would be, and actually was seen to be, caught by the motions which I then made of pressure upward; in other words, as would occur in active flexion of the joint. This thickened fold of membrane was about one fourth of an inch in breadth, and extended all across the patellar surface, and hung free half an inch when the patella was lifted up, or when pressed upon by the patella was fully an inch long on its free surface (see Fig. 1) and then was reduced to about one eighth of an inch in thickness. With the forceps and scissors the entire mass was removed from a rather broad surface on the upper-joint surface of the patella, that is to say, over a space of one-third of an inch in diameter at its widest part. Slight oozing of blood followed, which was controlled by the pressure for a short time of an antiseptic sponge. The cartilage underneath the outer edge of the patella was somewhat irregularly grooved, but nothing was done to this. The joint, which had now a small amount of blood in it, was washed out with a 1 to 40 carbolic acid solution. An India rubber drainage tube was carried just within the joint, below the patella, and the incised synovial membrane sewn up from this point to its upper end by a continued catgut suture. The divided skin and fascia were then closed to the point of drainage by deep silk interrupted sutures embracing both tissues. Iodoform gauze and sublimate dressings were applied around the joint, and the limb placed in a Volkmann's splint. This was chosen rather than a plaster-of-Paris bandage over all the dressings, as meeting easier the needs of the case, as it was intended at the end of forty eight hours to remove the drainage tube. No reaction followed the operation and at the end of the second day the tube was taken out and the stitches removed. Then a small piece of iodoform gauze was introduced down to the synovial membrane at the point where the drainage-tube had rested. The leg and thigh were then encased in a plaster-of-Paris bandage over the antiseptic dressings.

On the thirteenth day the splint was removed, the wound found all but healed, and the patient thereafter was allowed to move the limb slightly in bed. On the eighteenth day the patient walked on crutches, slight motion of the knee being allowed. At the end of five weeks, some limitation of flexion being present, the patient was given laughing-gas, and with slight pressure some resisting adhesions about the upper angle of the wound were overcome, after which full motion of the joint was obtained. The patient has from that time to this done well, having regained the power of the limb, some slight sensations being, however, met with in going up and down stairs.

CASE II.—A single woman, aged thirty-six, who gave a history of rheumatism in both knee-joints seventeen years previously, which was repeated four years ago, and followed on this last attack with complete recovery within six months. She is a laboring woman and uses her knee a good deal during her housework, but does not remember to have hurt the joint at any time. Her present trouble commenced in January, 1891, with swelling and inflammation of the left knee-joint. The joint was distended and the surrounding tissues were red and painful. The pain was quite severe. She was kept by it in hospital nearly a month. Last June she first noticed a peculiar grating sensation when the joint was moved, and after this time the joint would become caught and locked at a point midway between flexion and extension. An attempt at further flexion would frequently cause considerable pain. The unlocking was only to be accomplished after the foot rested upon the ground, when the leg was extended in a straight line. It could not be bent without giving pain, unless she first placed, as before stated, her heel to the ground. With the quadriceps rendered lax in complete extension, and the patella crowded from below upward, a sense of jumping and resistance is to be distinctly felt. My diagnosis, from the experience obtained in my first case, was that there was a fold of membrane probably extending across the patella, or on the anterior aspect of the femur.

She was admitted into my wards, at the New York Hospital, on February 22, 1892, and the next day, under ether, an incision was made, the limb being extended in the long axis of the limb along the outer border of the patella about three-quarters of an inch from the bone. The joint was first opened at its upper part and the synovial membrane incised down to the level of the sub-

patellar fat. With a blunt retractor introduced into the joint, so as to elevate the quadriceps tendon above the patella, a beautiful exposure of the bone was obtained, and a transverse band, running across the upper third of the patella, was found, of what appeared to be a hypertrophied epithelium of the cartilage, which presented itself as an elongated fold hanging downward a distance of nearly three-quarters of an inch. On the corresponding surface of the femur was found a smaller but similar fold, about three-quarters of an inch from the edge of the cartilage, which was no more than half an inch across, attached just above the intercondyloid notch (see Fig. No. 2). These growths were removed without difficulty by

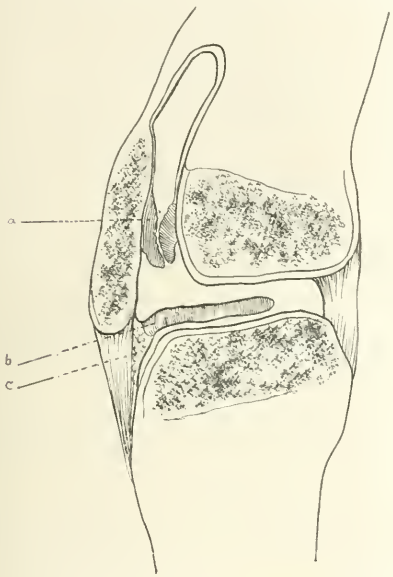

FIG. 2.—Folds Entirely Across Patella and on the Central Portion of Femoral Articular Surface. *a*, opposing folds, causing painful locking in flexion; *b*, semilunar cartilage; *c*, subpatellar fat.

a toothed forceps and scissors. The synovial membrane was then closed by a continued catgut suture to its lower border, where a couple of strands of silkworm gut were left to act as a drain. The skin and fascial tissues were secured by silk sutures. Antiseptic dressings and a plaster of-Paris splint were applied.

On the third day the patient complained of considerable pain. The temperature rose to 101° F. The dressings were removed and the joint found distended with fluid. Drainage was not freely accomplished by the strand of silkworm gut. This was removed and the opening in the synovial membrane slightly enlarged by a forceps. Clear synovial fluid readily escaped. A strand of iodoform gauze was allowed to rest against the synovial opening, and the dressings and splint reapplied. Pain immediately subsided. From that time convalescence was uninterrupted. At the end of three weeks she began to move her joint, which was stiff, and active and passive motions were resorted to. The adhesions yielded daily till the movements of the joint were fully restored.

The report of the Pathologist of the hospital in both cases was that the tissue removed was composed of a fibrous mass arranged in loose, wavy bundles throughout, in which were scattered round, oval, and spindle nuclei. No blood-vessels were found.

The mechanical impediment to the satisfactory motion of the joint in these two cases appears to me to have arisen, in the first place, probably from a traumatism which resulted in an effusion of blood, which either alone or by subsequent inflammatory action determined the formation of what has been happily described by Sayre as a joint blood blister. This loosened layer of epithelium, under the motions of the joint, was subsequently converted into a fold which produced the mechanical obstruction. In the second case the etiology may be more correctly referred to the rheumatic trouble, of which she gave a tolerably clear history. Though the first case was involved with considerable doubt in its diagnosis from the absence of any experience in this condition of affairs, yet attention was early drawn to the peculiar symptom of the difficulty after extension, of not being able to flex the limb without first bringing the action of the extensor muscles at an end by resting the heel on the floor, together with the singular jumping sensation which could be imparted to the patella when it was rendered free from muscular tension. These facts in the second case made the diagnosis comparatively easy.

This last patient, nearly two months since the operation, as you see, has a fairly satisfactory motion in the joint.

MICRO-ORGANISMS OF THE MOUTH.[1]

By JOSEPH H. LINSLEY, M.D.,

PROFESSOR OF PATHOLOGY AND BACTERIOLOGY, MEDICAL DEPARTMENT UNIVERSITY OF VERMONT; PATHOLOGIST TO THE NEW YORK INFANT ASYLUM, ETC.

MR. PRESIDENT, AND GENTLEMEN OF THE VERMONT STATE DENTAL SOCIETY: I have many times had the misfortune to be obliged to seek the aid of members of your profession, and the treatment I have sometimes been subjected to by them, while very generally resulting in my benefit, was of a very intense and extractive nature.

I have never anticipated being especially called upon to attempt an elucidation of any subject having a direct bearing on the details and operative work incident to the practice of your profession, and even an intelligent discourse on the theme of which I speak to-day would, but a few short years ago, have been practically impossible and excited but little interest.

But when a representative of your Society, four or five weeks ago, solicited of me a paper on "Bacteria of the Mouth," to be presented at the present session of your Association, I consented to his proposition with pleasure, more especially as I had intended, shortly, to undertake some bacteriological investigations in this direction. I very much regret the limited amount of time I have had in which to properly conduct many practical researches into some of the surprisingly numerous varieties of micro organisms which either find their habitat in the oral cavity, or are simply resting strangers, or loungers, as I might say, in this locality. While I shall exhibit to you some flourishing so called "pure cultures" of bacteria whose ancestors were removed from carious teeth, inflamed gums, and improperly cleansed "grinders," I have, necessarily, been obliged to resort to the latest text-books[2] on the subject, and to the various papers and articles which have recently appeared in medical and dental periodicals, both domestic and foreign, for the recognized varieties of germs infesting the mouth, their relatively respective frequency, etc.

To accomplish more than this, under the circumstances, was impossible, and the procuring of even the scanty material which I shall present to you exacted much more time and labor than you might at first imagine.

It is an interesting fact in the history of bacteriology that the first authenticated record and drawings of bacteria were made from micro-organisms discovered in mucus from the human mouth, by Leewenhoek, in 1683. From this time until about 1860 but little progress was made in this subject, and the rapid strides and the accumulation of important data accomplished in recent years has been very largely due to the improvement and perfecting of optical instruments. The fortunate dis-

[1] Paper read before the annual meeting of the Vermont State Dental Society, at Burlington, Vt., March 17, 1892.

[2] Miller: Micro-organisms of the Human Mouth.

covery, by Koch, of the use of artificial, solid, transparent food media, was of scarcely secondary importance in the development of bacteriology, by facilitating the separation, culture, and examination of germs.

A brief description of the more common culture-media used for separating and growing organisms of the mouth, together with the methods employed in obtaining pure cultures, will be of interest to those of you who are unfamiliar with the details of bacteriological investigations.

Nutrient Gelatine. This is composed of beef-juice, or beef extract, to which is added from five to twenty per cent. of best French gelatine, one to ten per cent. of dried peptone, and one to twenty per cent. of common salt. The reaction must be neutral, or very slightly alkaline. The addition of one to two per cent. of sugar improves the medium for the growth of mouth bacteria.

This material is easily prepared,[1] and is largely employed, especially for plate or dish cultures. It is unfit for use in the incubator, as the gelatine is liquefied at temperatures above 25° C. The characteristic growth of many bacteria is better exhibited on this substance than on the following.

Nutrient Agar-Agar. This is prepared [2] similarly to the foregoing, only that one to two per cent. of agar-agar is used, instead of the five to twenty per cent. of gelatine. (For detailed directions for the preparation of these media reference to the text-books on bacteriology is advised.)

Boiled Potato. This is a very simple and valuable nutrient medium. Any sound potato can be used, excepting those which crack open, or become mealy, on boiling. The potato is carefully washed and scrubbed with a stiff brush (an ordinary nail-brush answers very well), and the "eyes" and any unsound portions removed; it is then soaked for one hour in a 1 to 1,000 bichloride of mercury solution, and finally boiled in a steam sterilizer, or cooking "steamer," for one-half or three-quarters of an hour. It is then placed in a moist chamber, or covered glass dish, which has been sterilized, and in the bottom of which has been placed a piece of filter- or blotting paper, slightly moistened with a 1 to 2,000 bichloride solution. If the proper precautions have been observed in their preparation potatoes thus treated will remain germ-free indefinitely, and can be used at any time at a moment's notice, for the planting of material from which cultures are desired.

Many bacteria exhibit their most characteristic growth on this medium, and but few germs are known which refuse to exist upon it. Occasionally a micro organism is met with which requires for its full development a different soil from any of the three media just enumerated. In such cases other substances are used, such as sterilized blood-serum, starch-paste, boiled hen's egg, etc.

Liquid media are also employed in the cultivation of micro organisms generally, as well as for those from the mouth, but more especially for studying the progress and phenomena of putrefaction, fermentation, decomposition, etc., occasioned by the action of bacteria. Such media are bread-juice, peptonized beef-bouillon (to which has been added 2 per cent. of sugar, with occasionally the addition of starch), urine, milk, watery extracts of various plants or grains, juice of fruits, saliva (to which some nutritious substance has been added), etc.

Pure cultures are obtained by transferring a minute quantity of a "colony" from a glass plate or Petri dish, on the end of a sterilized platinum needle, to a tube of nutrient medium, where it is "planted," by either thrusting the needle directly through the middle of the solidified culture-medium in a test-tube, then twisting the needle a few times between the thumb and fingers, and carefully withdrawing same (the so-called "thrust," "puncture," or "stab" culture), or by drawing the point of the impregnated platinum needle, which has been slightly bent, across the surface of the medium, which has been allowed to solidify in the tube in an oblique direction (the so-called "scratch" or "surface" culture).

Considerable work and investigations in this line can be done by the practising dentist or physician without investing in an expensive outfit. At least it is quite practicable for any practitioner, who desires to determine the existence of any particular species of micro-organism in certain cases, to himself inoculate a prepared tube of gelatine, or agar, with the suspected material, and send the same immediately to a bacteriologist for further treatment, examination, etc.

The following is a procedure I have employed in the investigations of this subject, and is, as you will admit, exceedingly simple and quite satisfactory. I use the glass phials of various sizes used by some wholesale drug houses, for holding physicians' samples of pills, parvules, tablets, etc. These phials are sterilized, filled for from one to two centimetres with sterilized gelatine or agar, and their mouths closed with the ordinary cotton-wool plugs. When a patient comes under treatment, having a lesion of the mouth, teeth, or gums, the bacteria of which it is desired to cultivate, the dentist sterilizes an excavator, by passing it back and forth through the flame of his spirit-lamp or Bunsen burner a few times, and carefully removes a bit of material from the mouth and pushes it just into the gelatine in the prepared bottle. The same day, at the first opportunity, this is sent to me, and dish cultures, etc., are subsequently made from the specimen.

To review all the varieties of bacteria which have thus far been described and obtained (over 100 species) from the buccal cavity, with their individual peculiarities, etc., would require several papers, each fully as long as the present one.

I shall therefore confine myself to the consideration of a few of the more prominent and frequently occurring varieties, and afterward offer some comments applicable, in a general way, to the subject.

It has been customary for many observers to classify every thread producing germ which they find in the oral cavity as "leptothrix buccalis." This is to be deprecated, as there are several bacteria of the mouth which form threads.

The name "leptothrix buccalis" (like "bacterium termo") designates no particular organism possessing peculiar characteristics, and the name no more deserves to be retained than "denticola," "Buhlmann's fibres," etc.; the less so, since it has always been the expression for an obscure and erroneous conception.

Morphologically, as well as physiologically considered, leptothrix buccalis has been regarded as a veritable wonder. It has been said to perforate and split up teeth, its elements to cause all kinds of diseases in the oral cavity, to penetrate into the lungs, the stomach, and other parts of the body, and everywhere to manifest a destructive influence. As absolutely nothing was known concerning the biology and pathogenesis of this organism, all sorts of wonderful properties were ascribed to it. It is, therefore, high time to banish this confusing name from bacteriological writings (Miller).

Miller suggests the name of leptothrix innominata for those germs of thread-like growth whose biology is too ill understood to place their relation to other bacteria of the mouth. Let us, for a moment, consider what the inducements are which the mouth, as a whole, offers to wandering homeless "bugs," that they so readily and promptly enter these premises, and not only obtain their own individual livelihood, but, unceremoniously, at once proceed to increase the members of their households. As pertinently stated by one observer,[1] the mouth forms "a kind of hot-house or forcing ground for their cultivation." Dr. Bergtold[2] says: "If one could find a perfectly sterile

[1] Woodhead: Bacteria and Their Products, p. 337.

[2] W. H. Bergtold, M.D.: The Mouth as a Centre of Infection, Dental Cosmos, vol. xliii., No. 2.

[illegible] can be obtained, already prepared, of Eimer & Amend, 205 [illegible] lifted up [illegible] inch long on its free surface the same firm.

mouth, he could also see at once that the opportunities for seeding it, so to speak, are excellent, in that every individual is more or less constantly taking in air and also food and drink through that channel, and in both these actions there are received numberless spores and other forms which later give us growths of bacteria."

The organic and inorganic substances found in the mouth, are the following:[1] 1, Normal saliva; 2, buccal mucus; 3, dead epithelium; 4, dental tissue softened by acids; 5, exposed pulps; 6, exudations of the gums, conditioned by the irritation of tartar, etc.; 7, accumulation of particles of food.

The carbohydrates and albuminous substances furnish the greatest nutriment for bacteria in the mouth, and are almost constantly present there at all times. They are found between the teeth, in cavities in the teeth, and also upon their surface, and in any depressions.

Perfectly pure, mixed, human saliva has no toxic properties, and in those cases which have been reported by Pasteur, Valpian, Gautier, and others, in which "unadulterated human saliva caused more or less morbid phenomena," it must be suspected that the samples used *were*, in some manner, contaminated.

Mixed with the various deposits of bacteria, etc., always present in the mouth, saliva may possess most energetic toxic properties, having many times proved fatal even, as abundantly demonstrated by numerous recorded cases. It is also probable that the saliva has far less antiseptic properties than is often ascribed to it, and the undisturbed growth of micro-organisms in the oral cavity would seem to sufficiently support this view.

The diastatic action of the ptyalin of the saliva, in changing starch into a variety of sugar, variously termed dextrose, maltose, or ptyalose, which, as soon as formed, produces an excellent culture-medium for those germs concerned in the process of fermentation.

According to Miller,[2] there are six different micro-organisms which are almost invariably present in every mouth. They are:

1. *Leptothrix innominata.* This occurs as thin, more or less zigzag threads. Found in the soft white deposit on teeth in every mouth. Is stained faint yellow by a solution of iodine in iodide of potassium solution slightly acidulated with lactic acid.

2. *Bacillus buccalis maximus.* Occurs as isolated bacilli, or threads, more often as "tufts of threads." Is the largest of mouth bacteria. Is stained brownish-blue, more or less deeply, with the iodine solution.

3. *Leptothrix buccalis maxima.* This occurs as long, thick, straight or curved filaments, somewhat similar to bacillus buccalis maximus. It is found in the mucous deposit upon teeth. Is not stained by the iodine solution.

4. *Zoaococcus vaginatus.* Occurs singly, or in chains of from four to ten cells. Chains have a sheath, and cells appear as flat disks, or as more rounded, even squares. Occurs in all unclean mouths. Not stained by the iodine solution.

5. *Spirillum sputigenum.* This is seen as rods, curved like commas, having very active spiral movements. Found in all mouths, especially in unclean ones. Is the soft deposit on the margin of inflamed gums of dirty mouths. Stains more readily than the foregoing.

6. *Spirochæte dentium* (*denticola*). Found as spirals of very irregular windings and unequal thickness. It is found under the margins of the gums, when covered with a dirty deposit, and slightly inflamed, or, in other words, gingivitis marginalis.

There are a great many mouth bacteria proper, not invariably found in every mouth, which are uncultivable, and whose pathogenesis is unknown. Among them Miller found a bacterium of enormous dimensions, in the mouth of a dog suffering from pyorrhœa alveolaris, which he has called leptothrix gigantea.

[1] Miller: Micro-organisms of the Human Mouth, p. 37.
[2] Ibid., p. 69.

There are also three or four kinds of germs from the mouth which give a blue or violet reaction with iodine, and from twenty to forty varieties which are cultivable, partly non-pathogenic, partly of unknown pathogenesis. The oral cavity is a favorite locality for many varieties of chromogenic, or color-producing, bacteria. These are widely diffused in nature, and occur abundantly in water, in the air, and various places.

In the mouth they are less numerous than the colorless germs, and probably on account of this preponderance the color is not visible when in this locality, but is readily developed during the culture of these micro-organisms on many of our culture-media.

Among the colors produced by different species of mouth bacteria, Miller gives a yellow, produced by at least eight kinds of bacteria; green, by 5; red, or reddish, by 3; blue, black, brown, orange, etc.

To study any of the bacteria microscopically, particles of matter containing them must be taken from the mouth and mounted directly on cover glasses, after which they may be examined fresh and unstained, or (after being carried through the flame of a Bunsen burner, or alcohol-lamp, three times) be stained and mounted permanently.

Many of the germs that have been found in the oral cavity are, of course, accidentally present, having been deposited just previous to an examination, and which would remain only a short period. The micro-organisms I have just mentioned as being termed "mouth bacteria proper" by Miller, are found in all healthy conditions of this cavity, but the variety and number is more or less greatly augmented when any morbid condition whatever occurs, such as inflamed gums, wounds, etc., of the mucous membrane of the mouth, dental caries, ulcerations, etc. Of these, Miller found, by inoculation experiments on mice, rabbits, and guinea-pigs, many germs the inoculation with which produced either death or a pathological condition of the animals thus treated.

These he calls "pathogenic mouth bacteria." Of the varieties separated, the following were studied more in detail: 1, Micrococcus gingivæ pyogenes; 2, bacterium gingivæ pyogenes; 3, bacillus dentalis viridans; 4, bacillus pulpæ pyogenes.

The first of these micro-organisms, micrococcus gingivæ pyogenes, was found several times in a case of pyorrhœa alveolaris, in the deposit around the teeth of a very filthy mouth. The second, bacterium gingivæ pyogenes, was found in the same mouth as the foregoing, and also in a suppurating tooth-pulp of a second person. Bacillus dentalis viridans, the third variety, was found in the superficial layers of carious dentine. In cultivation upon gelatine this bacterium produces a beautiful opalescent green coloring matter, which it imparts to the gelatine. The fourth bacterium, bacillus pulpæ pyogenes, was found in a gangrenous tooth pulp.

The inoculating material used was pure cultures of the different germs, mixed cultures, and gangrenous pulps, and the inoculations were made into pockets, beneath the skin of the animals, and by subcutaneous injections and injections into the abdominal and thoracic cavities. The pockets were made, as usual, at the root of the tail, and the injections with sterilized syringes.

Before giving the results of these inoculations, let us see what are the conditions necessary to be fulfilled in order to establish unrefutable proof of the pathogenic nature of any given bacterium.

According to Koch, a micro-organism must comply with the following requisitions before its pathogenic character is determined, the so-called "Koch's laws," or "rules:" 1. It must be proved to be present in all cases of the disease in question. 2. It must further be present in this disease, and in no other, since otherwise it could not produce a special definite action. 3. A specific micro organism must occur in such quantities, and so distributed within the tissues, that all the symptoms of the disease may be clearly attributable to it. 4.

After removal from the body of an affected animal, and its growth in pure culture, the inoculation of the latter into susceptible animals must produce the disease in question.

Miller's operations were followed by either redness and swelling, abscesscs, suppuration and gangrene of adjacent tissues, blood poisoning, and, in many cases, by death from septicæmia, peritonitis, pleuritis, etc. Inoculations with mixed cultures proved more dangerous than when pure cultures were used, and still more effective when gangrenous pulps were used, than with mixed cultures.

The diseases caused by the pathogenic bacteria of the mouth Miller considers under six heads, according to the point of entrance of the infection. 1. Infections caused by a breach in the continuity of the mucous membrane, brought about by mechanical injuries (wounds, extractions, etc.). These lead, either to local, or to general disturbances. 2. Infections through the medium of gangrenous tooth-pulps. These usually lead to the formation of abscesses at the point of infection (abscessus apicalis), but also sometimes to secondary septicæmia and pyæmia with fatal termination. 3. Disturbances conditioned by the resorption of poisonous waste products, formed by bacteria. 4. Pulmonary diseases caused by the inspiration of particles of slime, small pieces of tartar, etc., containing bacteria. 5. Excessive fermentative processes, and other complaints of the digestive tract, caused by the continual swallowing of microbes and their poisonous products. 6. Infections of the intact soft tissues of the oral and pharyngeal cavities, whose power of resistance has been impaired by debilitating diseases, mechanical irritations, etc. 7. Possible infections by the accumulations of the excitants of diphtheria, typhus, syphilis, tuberculosis, etc.

Dental Caries.—It has been proven beyond doubt, that decay of the teeth is caused by two different processes, namely: *a*, chemical; *b*, parasitical. The first is a decalcification of the enamel, or dentine, or both, caused by the presence of acids in the mouth, which have been formed from the fermentation of starchy and saccharine substances, resulting in a softening of these tissues, after which these latter form an excellent food-medium for many varieties of bacteria. The prevention of dental caries depends, first of all, upon strict cleanliness of the mouth, the importance of which can not possibly be overestimated; the details necessary for the proper fulfilment of the same it would be superfluous for me to suggest to you. Undoubtedly, good stiff tooth-brushes and plenty of clean water stand at the head of all measures of this nature. The next prophylactic means is the intelligent use of proper antiseptics.

By far the most perfect germicide known that can be at all employed in this connection is the bichloride of mercury, but the use of this substance is not without danger. It should not be used as a wash for the mouth in solutions of greater strength than 1 to 2,000, and even then care must be exercised in its application. Other antiseptics which have been recommended for the oral cavity, are salicylic acid, strength of 1 to 200, or 1 to 350, listerine, wintergreen oil, and like aromatic substances are suggested.

In this connection might be noted the germicidal properties of tobacco, either the juice of the leaf, or the smoke of the burning leaves. Certain it is, from results obtained by many experiments and observations, that tobacco-juice or smoke very speedily destroys bacterial life, but I would not, on this account, advocate its use, as the evil results of excessive indulgence in the "weed," more than counterbalance any possible benefits resulting from its antiseptic action on micro-organisms of the mouth.

In discussing the subject of infection, attention should be directed to the danger which exists from the spread of infectious forms of bacteria, that are liable to be present in the mouth, in various directions. It is not difficult, under certain circumstances, to excite an inflammatory process in the middle ear, the transmission of septic germs taking place through the Eustachian tubes; similar results may also occur from pyogenic bacteria being carried from the mouth to the throat, lungs, parotid gland, antrum, and even to the brain, as stated by Bergtold. When it is considered, that of all diseases of a parasitic nature, to which mankind is susceptible, dental caries is by far the most frequent, the possibilities I have just mentioned cannot be charged as being the improbable and unlikely speculations set forth by one who is "cranky" on the subject.

Upon reviewing the various literature on this question, especially those portions of it which refer to the dangers of infection between the dentist and his patient, I was much surprised to find no advice offered to the dental profession by competent bacteriologists as to the considerable (and ofttimes great) danger present to the patient by pathological conditions the dentist himself may be suffering from at the time of operating, and to point out the necessity of establishing, by legislative measures if required, laws or statutes which would prevent the occurrence of such dangers.

I refer more particularly to the jeopardy in which human life is placed when people are subjected to treatment by a practising tubercular dentist. This may seem to many of you a bit of superfluous advice, and you may retort that such a circumstance is beyond the bounds of possibility, but I assure you I have seen a tubercular member of your profession practising daily on unsuspecting, or ignorant patients.

My experience with dentists has been very limited, and therefore I am not in a position to make any assertion as to the frequency of such pernicious and dangerous proceedings; but the very fact that my slight, personal observations resulted in the detection of one such case naturally suggests a possibly more frequent occurrence of tuberculosis in practising dentists than might be supposed.

Since commencing the work incident to the preparation of this paper one of the local members of your profession has detailed another case, which was under his own personal observation, of a tubercular practising dentist.

The greatest danger, under such circumstances, is not, as some of you might imagine, in the infection of the patient by the transmission of the germs through the medium of the breath of the operator, but in the reception of tubercular material, which becomes dry on the handkerchiefs, clothing, linen, or instruments of the dentist. The prevention of such desiccation is so extremely difficult and impracticable that any consideration of it is useless. It cannot be effected, and hence it is not to be considered as a possible prophylactic measure to enable the victim of this malady to continue his professional work until physically unable to do so on account of the inroads of the disease.

It is not generally known that bacteria do not float in the atmosphere in the moist state, but only do so after desiccation, and then probably to no great extent, unless aided by more or less strong currents of air.

Tuberculosis is now almost universally considered to be an infectious disease, and of so contagious a nature that I candidly believe we shall, many of us, see the day when attention to preventive measures against possible infection from cases of this disease, will be as regularly insisted upon as are the sanitary requirements in cases of small pox, yellow fever, and typhus fever (with the exception of somewhat less vigorous quarantining) at the present day.

The period in which to accomplish this much desired treatment of tubercular cases, will depend upon the rapidity with which the laity, and professional men even, become educated to the full comprehension of the single and sole cause of the affection—the tubercle bacillus—and the proper realization of the benefits to be derived

from the adoption of such measures. And to the intelligent efforts and advice of the members of the medical profession, as well as to the great aid which you—members of the dental profession—can give by embracing each and every opportunity to inform your patients, especially influential citizens, as to the true character of tuberculosis, must the accomplishment of this end very largely devolve.

Of all the various ways by which tubercle bacilli find entrance into the human body (such as from the surface of the skin through wounds, by contusions, cuts, or otherwise; from the ingestion of milk and flesh from tubercular cows and animals, etc.), infection by inspiration, by the entrance of the dried germs through the mouth, and so on to the lungs, far surpasses in frequency all other methods of transmission. And this can only be accomplished when the medium on which the micro-organisms have been discharged from the body dries, or disintegrates, into powder or dust. For this reason the most dangerous source of infection is from handkerchiefs or cloths on which the sputum has been received (unfortunately a too common procedure), and on which it becomes dry in an exceedingly short time. Consequently by merely preventing the sputum of consumptives from drying the most important kind of infectious matter may be rendered harmless.

The first contradiction I have seen, by competent pathologists (who acknowledge the tubercle bacillus as the essential cause of tuberculosis), to the statement that the commonest source of infection is the inhalation of dried bacilli from handkerchiefs, linen, clothing, dust from the floors and ceilings of rooms previously occupied by tubercular subjects, etc., was recently made by Dr. J. West Roosevelt, of New York.[1] He maintained that "there was much more likelihood of getting an overdose of the virulent germs" (of tuberculosis) "through the alimentary tract, either by the ingestion of meat or milk, or in children by putting articles of every nature into their mouths, no matter where they may have lain," than by the manner which I have just described.

While recognizing the value of the opinion of so able an authority as Dr. Roosevelt, I am convinced that his statement will not be corroborated by the majority of pathologists and bacteriologists in this country, or on the continent. True it is that much needless alarm may be created in the minds of the public by the advocacy of too severe and unnecessary measures of prevention, such as quarantining, etc., by prejudiced and over zealous investigators, the effect of which would be the unjustifiable persecution of many poor victims of tuberculosis, and, as I just suggested, the only proper course to pursue in dealing with this question is by persistently and intelligently educating the minds of the public, as to the exact status of this matter.

Few pathologists at the present day believe in the theory of heredity as a cause of tuberculosis. It is a fact that the offspring of affected parents (especially when the mother) often regularly develop, sooner or later, the disease, but the explanation is to be sought in a general impoverished condition of the organism, as indicated by enfeebled assimilative and nutrient powers, which are quite sure to follow as the inheritance from unhealthy progenitors.

What I have just said in regard to transmission naturally leads to the most interesting and important problem in bacteriology, namely, that of immunity, and I ask your indulgence for a few moments, in order to state the theories at this time held in regard to this subject.

As you are all probably aware, two principal views are advanced to account for the difference of susceptibility possessed by different animals to the same micro-organism, and also that exhibited by the same animal to different germs. I might here state that immunity is of two principal kinds, to wit: *a*, natural, or "inborn;" and, *b*, acquired, or "artificial." The first of the theories of natural immunity is based on the chemical, germicidal properties of the blood-serum and tissue-juices of the body. The second, or "Metschnikoff's theory," attributes the resisting power which an individual or animal may possess to the so-called "phagocytic" action of the tissue cells of the body, more especially the colorless corpuscles, or leucocytes, of the blood.

Metschnikoff believes the presence or absence of immunity depends upon the ability or inability of the cells of the body to devour and destroy the bacteria. Such ability may be natural or acquired. In the latter case, the cells, where they have once had the opportunity of devouring attenuated micro-organisms with a milder poison which nature enables them to withstand, are so far accustomed to it that they can devour the most virulent material with impunity. This can be effected both by gradual adaptation, and also by a kind of selection, in which only the strongest, most vigorous cells remain and transmit the acquired faculty to their descendants. The leucocytes are but short-lived cells. A permanent resistance of the organism to a disease which it has once had, or against which it has been protected by inoculation, is, therefore, only conceivable, if we grant to the cells the power of transmitting an acquired property unaltered to their children, and their children's children. This hypothesis,[1] as must have been seen, presupposes an extraordinary docility in the protoplasm of the white blood corpuscles, to which it attributes something like feeling, thinking, and acting, a sort of mental perception. But if we raise no objection to this, there remain plenty of reasons for combating the phagocytic theory of immunity. In our opinion, the fact that it is essentially the excretions of the bacteria which produce, or are able to produce, immunity is difficult to harmonize with Metschnikoff's hypothesis; for if no living micro organisms are present, none can be devoured, to accustom the cells to the poison and prepare the way for resisting more virulent successors. To overcome this difficulty, it would be necessary to suppose that the reception of attenuated germs acts upon the cells only as a specific stimulant, to which they respond by a functional reaction, and that this stimulating power exists in the same degree, and works in the same manner also, in the bacterical products.

The theory of the germicidal action of the blood-serum, or plasma, is, I believe, supported by more weighty authority than is the ingenious one of Metschnikoff. I have thus forsaken the exact theme of my discourse from a belief that more benefit would be derived from the brief treatment of a subject at best only partly understood by the highest authorities in this branch, but which one who has devoted much time in practical investigations must, necessarily, be better qualified to handle than the average practitioner.

Would the time (and, perhaps, your forbearance also) admit, much profit might be had from the further discussion of bacteria of the mouth, but the vast extent of the subject renders anything but a superficial consideration of it impossible. As yet we are only on the frontier of the domain of bacteriology, and have only obtained a comparatively few facts, or details, of this most interesting and important kingdom. What data and facts investigations into the interior of this boundless area of unexplored territory of micro-organic life will place us in possession of, time, perseverance, and unremitting efforts will prove. We certainly have reason to believe that the knowledge of such points, at present undiscovered, together with their practical application, will be of inestimable value to mankind.

Compulsory Vaccination in Turkey.—According to the *Revue Médico Pharmaceutique* of Constantinople, the Turkish Government has decided to make vaccination compulsory throughout the Ottoman Empire.

THE TREATMENT OF SPINA BIFIDA BY EXCISION,

With Report of the Successful Removal of a Lumbar Meningocele from an Adult.[1]

By CHARLES A. POWERS, M.D.,

SURGEON TO THE NEW YORK CANCER HOSPITAL.

W. J. H—— a man aged thirty-five, consulted me in the early part of January, 1891, regarding a tumor of the back. He was afflicted at birth with a spina bifida, the tumor being the size of an orange during childhood. His mother had frequently pricked this tumor during the first years of life, dressing it with a "burnt rag." It gradually grew smaller and gave him no annoyance. Up to the age of twenty-eight he had had no vesical or rectal incontinence, no evidences whatever of any affection of the nervous system, except that after his fifteenth year he noticed that when the clothing or a bandage irritated the tumor, locomotion was somewhat interfered with. At twenty-eight years of age he gradually began to lose power in the legs. The right was affected first, and most extensively, the left being involved later. The heels dragged, and there was dull, aching pain and soreness about the hips, extending down the back of the thigh, this being worse on sitting. Occasionally he had had sharp pains in the loins, hips, and knees, sufficiently severe to throw him down. These came on at irregular intervals, perhaps once a month. Obstinate constipation, occasional attacks of urinary incontinence, at times difficulty in commencing micturition.

Examination.[2]—The patient is a poorly nourished, rather undersized man. He avers that he has never suffered with syphilis, and has never been given to excess in alcohol, tobacco, or sexual relations. He has had long periods of impotence, now has occasional erections. During the past year weakness has invaded the arms; he has some difficulty in raising his food to the mouth, some trouble in writing.

The right upper extremity seems to be affected to a greater extent than its fellow. He has no pains in the arms, but stroking them downward causes a congested feeling in the hands. There is at times a cold sensation across the chest from shoulder to shoulder. About one year ago he would "lose" his arms and legs while in bed, but this symptom has passed away. He has never had cincture feeling, nor cushiony sensation in the feet. He sleeps but poorly. He has had diplopia at a distance during the past year and a half.

Examination of the eyes reveals, in the right, the veins of the fundus dilated; in the left the optic nerves of a whitish, atrophied appearance; pupils small, not immobile.

The walk is ataxic and paraplegic; the arms are very ataxic; sensation to touch is much impaired below the nipple line. The reflexes are abolished.

There is a flattened, Scotch-cap shaped tumor a little to the right of the median line, opposite the last lumbar vertebra. This is thick above, tapering below. It is about four and one half centimetres in diameter, constricted at its base. There is a cicatrix near the apex, and there are one or two areas of superficial fluctuation. There seems to be no deep fluctuation. The tumor has a pulpy, leathery feel. It is only tender when roughly handled.

During several years the patient had been under the care of neurologists in a neighboring city. He was referred by me to Dr. R. W. Amidon, who, after a period of observation during which he administered potassic iodide and spinal cauterization, advised removal of the tumor. Under date of February 18th, Dr. Amidon writes: "While not pretending that the tumor causes the present condition, I am firmly convinced that, as a source of continual sensory irritation, it may much aggravate his spinal symptoms, and that its removal is certainly desirable."

On February 23d, under ether, a vertical incision was made in the tumor. Two or three small, superficial cysts were opened. At a depth of 1.5 ctm., and at about the middle of the tumor, a cavity the diameter of the index-finger was encountered, leading through a somewhat constricted neck to within the spinal canal. A probe introduced through this neck passed easily above and below. The lining surface of the sac was smooth and glistening. The cavity contained a little clear, serous fluid. There was no escape of fluid from the opening which led within the spinal canal.[1] There were no nerves in the sac.

The tumor was removed, the neck of the sac ligated and sewn up with catgut, and the wound closed. A relaxation incision was necessary in order to coapt its edges. Complete primary union followed, and the patient was about on crutches in his usual manner in a moderate length of time.

He returned to his home in Boston and placed himself under the care of Dr. J. J. Putnam, who wrote me on December 16, 1891, that his general condition was better than before operation. He had improved use of the upper extremities, and could balance himself on his crutches to better advantage. Control over the bowels was improved.[2] Mr. H—— insists that the removal of the tumor has been "a source of great comfort."

To sum this case, then, we have: a congenital spina bifida, with a small tumor which gave little trouble in childhood. No nervous element until fifteen years, then slight interference with locomotion. At twenty eight years, development of a progressive ataxic and paretic state, possibly due to continuous irritation of the tumor by the clothing about the waist. Successful and simple removal of the tumor a source of comfort to the patient, and followed by improvement in the ataxic symptoms, which improvement may or may not have been due to this removal [and which seems to have been temporary—see statement of Dr. Putnam, footnote [2]].

It would not seem profitable to describe here the various forms of spina bifida, or the measures adopted for the relief of the affection. Of recorded excisions in adults I am able to find but three,[3] and but one of these seems worthy of special mention. This was reported in the *Lancet* of last year[4] by Mr. H. H. Clutton. It concerns a young woman of twenty-one years, who consulted Mr. Clutton in 1887 regarding a tumor twenty inches in circumference, situated in the median line over the last lumbar vertebra. It had existed since childhood, and had shown steady increase in size until five years previously, at which time it had ceased to grow. It was only troublesome when she inadvertently turned upon her back while lying, but at such times she would have faintness and headache.

There were no paralytic symptoms whatever. The young woman wished to marry and desired removal of the tumor. Mr. Clutton declined to interfere, though the patient repeatedly besought his aid, until three years later. At that time she was worse, anxious to marry if relieved of her deformity, and the tumor showed an increased size. It was removed, an aperture the size of a pencil-case found leading to the spinal canal, a few nerve-filaments about its edges. Some leakage of serous

[1] Read, in part, before the Surgical Section of the New York Academy of Medicine, April 11, 1892.

[2] I am indebted to Dr. Amidon for descriptive notes.

[1] I was unable to thoroughly satisfy myself as to the exact nature of the bony defect through which the neck of the sac passed. So far as I could judge, it was a gap at the site of the right lamina of the last lumbar vertebra.

[2] Since reading this paper I have received an additional note from Dr Putnam, who writes, May 4, 1892, that the pain which was present in the sacral region and buttocks before operation has increased of late, and that the patient seems to be gradually losing ground. The improvement was, then, temporary. Dr. Putnam believes the man to have hydromyelia.

[3] Cases 18 and 26, Table A. An additional case may be found in the report of the London Clinical Society, *vide infra*.

[4] Lancet, 1891, ii., p. 803.

fluid followed the operation, yet the wound healed kindly and the patient went home at the end of six weeks. No paralysis had followed at time of report, one year after the operation.

We see but very few cases of spina bifida in adults, for the reason that the natural course of the untreated disease is a fatal one. Thus, in the exceedingly thorough and painstaking report of the committee appointed by the Clinical Society of London (1885), but fourteen out of sixty traced cases were known to have undergone spontaneous cure. As was well said, however, these figures form a very uncertain guide, as very many infants perish yearly from this trouble whose cases are never recorded, while those who do survive, with or without treatment, are pretty certain to be placed on record. In this way, then, the report of Demme is of greater value. He observed fifty seven cases, and states that of the thirty-two for whom no operation was undertaken not one was alive at the end of two years.

Confronted, then, with such an extreme mortality, one is forced to the conclusion that in suitable cases some procedure must be undertaken with a view to saving life, and is led to weigh the methods which have been proposed. In the exhaustive Report of the London Clinical Society, to which reference has been made, strong commendation is accorded the iodo-glycerine injection of Morton. Seventy-one cases collected by the committee showed a mortality of 38 + per cent.[1] In this report, further, the treatment by excision is condemned as unsafe, though the 7 deaths out of 23 cases give a mortality of but thirty per cent, a death-rate considerably less than that (38 + per cent.) attending the Morton injection.

Since the appearance of this report a number of writers have placed on record cases subjected to excision, and the consensus of opinion of these authors seems to be in its favor. It is evident that it is to be resorted to in selected cases only—cases in which the general condition of the patient is good, in which paraplegia is absent, in which the vertebral fissure is of moderate extent and the communication between the sac and the canal narrow.

In simple meningocele one may remove the tumor, suture together the serous surfaces at the neck of the sac, and close the wound. Under suitable conditions such procedure should not be attended by very great risk, all possible precautions being taken to prevent subsequent "leakage." If the case be one of meningo-myelocele, one may cut off nerves which terminate in the sac, or endeavor to loosen and replace within the spinal canal those which course it. Bayer[2] recommends loosening the muscles on either side the spine, and bringing them together in the median line to strengthen the resistance over the bony gap.

Dollinger[3] has successfully practised osteoplasty, bringing the laminæ together to supply a defect due to lack of the posterior segment of the arch of the fifth lumbar vertebra, and a similar case is reported by Mayo Robson.

Périer[4] reports, five months after operation, a case of lumbar spina bifida, in a baby of seven weeks, cured by Berger (Case 33, table A), who implanted in the spinal gap a segment of bone from a rabbit's scapula. Périer thinks it probable that the bone has been absorbed, but surmises that it may possibly have served as substratum for a firm tissue in which ossification may take place later.

In a most interesting and instructive paper of last year, Bradford,[5] of Boston, reports personal cases of excision, together with a number of other operations which he has been able to gather from literature published subsequent to the report of the London Clinical Society in 1885, the total exhibiting a mortality, due directly to the operation, of 29 + per cent.

To these cases collected by Bradford I am able to add others, making a total number of 34. From these 34 cases 3 are withdrawn in which the cause of death or the result seems indefinite, leaving 31. These present 7 deaths due directly to the operation, a mortality of 22.58 per cent.[1]

13	Ibid.....	7 weeks.	Injection of Morton's fluid.	Recovery.
14	Snowball, Austral. Med. Jour., 1889, p. 195.	3 weeks.	Injection of Morton's fluid.	Recovery.
15	Morton, Bristol Med. Chir. Jour., March, 1892, p. 14	4 months.	Injection of Morton's fluid.	Death.

Fifteen cases, 4 deaths. 26.66 per cent. mortality.

We thus see that the death-rate attending excision is decreasing, that the recorded cases of the past seven years show a mortality below that attending the injection of Morton's fluid (22.58 per cent. as against 26.66 per cent.) in the cases published during the same time, and but slightly above that in the results attained by Mr. Morton himself[1] (20.7 per cent.).

From these facts it would seem that the conclusions of the Clinical Society's Committee, to the effect that "The plan of treatment by injection is the best with which we are acquainted, and the only one which we feel justified in recommending,"[2] are not at this time entitled to being considered authoritative.

The treatment by excision must certainly be thought the most rational, the most scientific. Improvement will follow more careful selection of cases, the choice of an appropriate time for operation, and added knowledge in technique. The results thus far attained are certainly encouraging, and lead to the belief that the operation is one which will find added favor in the future.

[1] I do not doubt that it has been used in many other cases, these are all which I find recorded.

ON THE USE OF IODINE TRICHLORIDE IN SURGERY.

PRELIMINARY COMMUNICATION.

BY WILLIAM T. BELFIELD, M.D.,

CHICAGO, ILL.

LAST fall there appeared, in reports of bacteriological work from Berlin, certain allusions to the trichloride of iodine which induced me to investigate this agent clinically. The results are such as to require me to call attention to the apparent value of this substance in arresting the two bacterial processes most commonly met by the surgeon—tuberculosis and suppuration.

Since the trichloride has as yet no place in the Materia Medica, a word as to the substance itself seems appropriate: it is, as the name indicates, a simple compound of iodine and chlorine (formula, ICl_3) made by passing chlorine gas over iodine; the result is a reddish crystalline substance emitting an odor of chlorine. It dissolves in its own weight of distilled water, and almost as readily in alcohol; either of these solutions mixes freely with glycerine in any convenient proportion. Though a union of two closely allied elements, it is a stable compound; I have kept the crystals and various solutions for five months unchanged.

When a few drops of a solution of the trichloride fall into normal urine, instant decomposition ensues, both chlorine and iodine being liberated in a nascent state; a deep brown color (iodine) and bubbles of gas (chlorine) at once appear, while a mixed odor of the two elements becomes plainly perceptible at the mouth of the tube. To my colleague, Dr. W. S. Haines, Professor of Chemistry and Toxicology in Rush Medical College, I am indebted for the demonstration that this reaction is caused not by any of the urinary salts, but by an organic constituent of the urine, probably mucin. This clue led to the revelation that the same decomposition is effected by contact with any animal matter in solution—including pus, blood, saliva, infusions of meat, etc. The extreme sensitiveness of the trichloride to animal matter compels the use of distilled water for its solution; since ordinary hydrant water (though Chicago water is by no means the vile fluid pictured in certain Eastern papers) decomposes the compound in a few minutes.

The well-known bactericide properties of both chloride and iodine suggested, *a priori*, the surgical value of the substance which liberates each of these elements in its nascent state upon simple contact with the tissues. I have made tests with different bacterial cultures, and find, for example, that a one per cent. aqueous solution rapidly sterilizes cultures of the ordinary pus-producers—staphylococcus and streptococcus. Yet we have learned by experience, particularly Geppert's revelations concerning the bichloride of mercury, not to transfer deductions from the test-tube to living tissues. Satisfactory

[1] The Treatment of Spina Bifida by a New Method. London, 1887, p. 212.

[2] Clinical Society's Transactions, vol. xviii., p. 385.

proof of clinical value must be furnished on these tissues directly.

During the past six months I have used the trichloride, at first occasionally, later continually. The cases may be summarized as follows :

1. *Surgical Tuberculosis.*—Iodine with its compounds has long been the surgeon's chief remedy for local use against tuberculosis ; I therefore expected decided effects from the trichloride in these cases, and have not been disappointed. Of a considerable number so treated, comparatively few can be adduced as proof because in most of them guaiacol was also administered internally ; since the latter is an unmistakably powerful agent against surgical tuberculosis—as I know from a year's experience with it—the benefit derived from the mixed treatment cannot be ascribed solely to the trichloride. The following cases were, however, treated with the trichloride alone : Two of bladder tuberculosis (diagnosis confirmed in one case by presence of the bacilli, in the other by discovery of a distinct ulcer) ; 2 of epididymis tuberculosis with fistulæ (the latter rapidly closing under hypodermic injections, for the first time in years) ; 1 of tubercular abscess of prostate ; 6 of suppurating tuberculous cervical glands ; 2 of tuberculosis of knee-joint in children ; 1 of tubercular empyema.

2. *Suppuration.*—A miscellaneous line of cases, including infected wounds, abscesses, and malignant ulcerations.

3. *Ammoniacal Cystitis.*—Six cases caused by retention from prostatic enlargement.

4. *Venereal Sores.*—A detailed account of individual cases would be out of place in this communication ; the results may be summarized in the statement that, in a reasonably extended experience and observation, I have never seen tuberculous processes so rapidly subdued by iodoform, nor suppuration by hydrogen peroxide, iodoform, or any other agent.

These cases are too few to be conclusive; yet the uniform and unusually rapid effect warrants the presentation of the trichloride for extended trial. It seems to combine the valuable properties of iodoform and hydrogen peroxide, with advantages over each peculiarly its own ; it appears more energetic than iodoform in arresting processes dependent upon bacterial agency, both suppurative and tuberculous ; it is soluble in water, and hence capable of hypodermic use as well as of gradation from innocuous dilution to caustic effect. Incidentally it is cheaper and far less offensive to the nostril. Over the peroxide it has the advantage of stability prior to use ; prolonged contact with the tissues; the power to sterilize not only pus, but all moist animal matter ; and adaptability to use on gauze.

Its disadvantages as compared with these agents are its caustic properties in strong solution, and the deleterious influence on instruments and clothing. Doubtless iodine intoxication could be induced by large quantities, but no instance thereof has as yet occurred to me.

I have employed it in the following forms : For hypodermic use, one-tenth to one-half per cent. solution in distilled water alone, or water four parts, glycerine one part. (In experiments on animals I have seen sloughing follow the hypodermic use of a two per cent. solution.)

For instillation of deep urethra and irrigation of bladder, and for injection of serous cavities, the same solutions. For suppurating wounds, irrigation with one to five per cent. solution in water, either alone or with glycerine. For putrid surfaces (cancerous), venereal sores, etc., five to twenty per cent. solution in equal parts of water, glycerine, and alcohol.

Solutions stronger than five per cent. usually cause decided smarting in ordinary wounds. The crystals are caustic to denuded surfaces. Gauze sterilized by boiling, immersed in one to ten per cent. aqueous solution and dried, retains the compound for an indefinite time.

PRIMARY CONSECUTIVE AMPUTATION AND RESECTION IN TRAUMATISMS OF THE EXTREMITIES.[1]

By THOMAS H. MANLEY, M.D.,

NEW YORK.

In a former period the rules governing the time at which an amputation should be performed were precise and definite. There was, however, a cardinal distinction recognized with regard to the circumstances under which the injury was sustained, whether it were in military or civil life. Since the discovery of constitutional anæsthesia and improved methods of dressings, a marked revolution has been wrought in the management of such crushing, disorganizing injuries of a limb as may give rise to the question of amputation. Ollier, in his extensive experimental and clinical researches and observations, has discovered that the young healthy bone possesses great regenerative power, and that the field for practical osteoplasty in traumatisms involving the bones was a very large and fertile one. It was, besides, demonstrated by Lister, that by the employment of chemical solutions septic infection could be often prevented. The outcome of all this has been that the necessity for complete disseverance of a limb at present seldom arises.

My purpose on this occasion is to describe the conditions under which a primary consecutive amputation or resection should be performed in serious injuries.

I have elsewhere stated, and now reiterate it, that a primary amputation should never be resorted to in civil life unless all the important structures of the injured limb have been thoroughly destroyed ; when the knife is employed simply and solely for the purpose of completing the detachment of the fibres which hold the parts together.[2] When the parts are extensively shattered, yet one is in doubt as to the vitality of the distal tissues, nothing is lost by waiting. In a city like ours, so extensively covered by iron rails, where the number of the injured who have been run over is annually increasing, this conservative course of delay is of infinite value. For, when one has been brought into the hospital after having been run over on the street, it very often is utterly beyond the power of any surgeon to then estimate just how much has been destroyed, or where the precise line of demarcation will form. Certainly in those compound shattering fractures which open into joints, or involve the thigh, there will be little hope of gaining anything by delay ; but in the growing child, with resection of the joint, a fairly useful limb might be secured.

A classical primary amputation, then, should not be practised except in very rare cases. The principle of preservation must be constantly kept in view in these disorganizations of the extremities from accident. But is not our patient exposed to great danger by a considerable delay, through hemorrhage, pain, infection, or gangrene? Practically none, when proper precautions are observed. With an extensive experience in this class of cases for the past ten years, I have never seen a single case in which any ill-effects occurred in consequence of waiting. There is a class of cases, however, in which everything is thoroughly and completely destroyed at, and beyond, the seat of injury, where there is no contra-indication to an immediate amputation.

The ordinary text books on surgery have a certain set of rules for one's guidance in amputations. These have a limited range of application in pathological conditions requiring the disseverance of a limb ; but in extensive traumatic disorganizations they are wholly useless. In those primary amputations there is no guide like experience in enabling one to secure a useful flap. In spite of every precaution the overlapping integuments will slough in varying degrees, at times leaving a wound which must heal by granulation, or, possibly the bare, denuded ends

[1] Read before the Surgical Section of the New York Academy of Medicine, February 8, 1892.

[2] Resection as a Substitute for Primary Amputation, New England Medical Monthly, October, 1891.

of the bone may ultimately require a future resection. But most lamentable of all are those in whom we may secure prompt primary union and an artistic but useless stump.

In consecutive amputation after injury we can usually proceed on quite precise lines. The patient has now survived the shock, the circulation is re-established, the muscles have recovered their contractility, and we are in a position to select such a form of flap as may seem most desirable. It may be well, however, to note a few peculiarities here about flap- or stump-making in a general way. We know that the flap which is completely freed from its muscular connections is less apt to retract and give rise to a painful, sensitive stump through tension on the end of the bone. But in the feeble, or with those whose circulation is languid, this cutaneous flap is very prone to slough. The muscular, on the contrary, is the most vascular and may be depended upon to amply nourish the periphery. To overcome the immediate tendency to active muscular contractions, adhesive straps should be employed, which should be so adjusted as to press the redundancy of muscular tissues in the direction of the stump.

These measures should be continued until thorough reaction, with fatty interstitial degeneration of the fasciculi, is established and atrophy has commenced. Since the antiseptic era, until the reaction set in against the new doctrine, the aim of the operator has been to secure primary union, after consecutive amputation particularly; to favor the absorption of the detritus, which results from an extensive laceration and contusion of living tissues, rather than in the times which antedated this period; to effect their elimination through a vent in the wound, by drainage and moderate suppuration. This has been accomplished by the substitution of one irritant for another, or chemical for an atmospheric irritant; for every antiseptic solution worthy of the name is a positive irritant, and is a foreign substance. The soft parts manifest a singular tolerance for those irritants, but on the osseous tissues they often act with a destructive energy. This is the reason that periostitis, osteitis, and osteomyelitis have so often supervened in those aseptic stumps.

I once had a female patient, on whom I first performed an ankle-joint amputation. Result, prompt union, handsome but useless stump. Second amputation in a year, just below the knee-joint, rigorous antisepsis. Result, primary union, prompt, but a painful, sensitive stump, requiring the constant use of morphine. Third amputation, lower third of the femur, no antiseptics, but an abundance of sterilized water employed. Result, union with a little suppuration, but a non-sensitive, comfortable, useful stump. So convinced am I of the general baneful influence, particularly, of mercuric solutions on living osseous tissue and bone marrow, from many observations, that at the present time, unless purulent or putrefactive processes are present, I employ none of them. The drainage-tube, for a few days after amputation, serves a useful purpose. In many cases, however, its presence excites an irritation, so that, as a routine custom, drainage should not be employed in amputations. The abundant, fluffy, absorbent dressings of Samson Gamgee are of inestimable value in amputations, by exercising a moderate pressure over the wound, maintaining a uniform temperature, excluding irritants, and absorbing the residue of inflammatory products.

Resection in traumatisms of the extremities which extensively involve the bones, is an old expedient in surgery, but it was never very extensively employed until the present century. Experimentation on the osseous system of anæsthetized animals, and opportunities to proceed with leisure and deliberation on unconscious man, have greatly widened the range of osteoplastic operations.

Osteoplastic procedures are particularly applicable in that class of cases in which in former times prompt recourse to amputation was the rule. As examples, I may be permitted to mention two of the many very aggravated cases in which the expedient was successfully resorted to by myself. In one, the upper fourth of the humerus was shattered into a score or more of fragments by a heavy charge of buckshot. Patient, man of thirty; immediate resection; recovered with false joint, but so useful a limb, that he has been able to follow his usual trade as a carpenter since he left the hospital. In the other patient, lad of five years, the whole of the tibia was shattered and shelled out of the periosteum, from knee to ankle, its periosteum and both articular heads remaining. The fibula sustained two fractures also. Resection, immediate. Result, entire regeneration of the lost tibia, and so much functional restoration that he now walks with scarcely a limp. From these extremes I have, very many times, substituted resection for primary amputation in nearly all the bones of the extremities from the phalanges up, except the femur. This is the one bone of the extremity which will not tolerate manipulation with impunity; hence, in compound, comminuted fractures of it, when the system is in condition to bear it, amputation should be promptly performed.

In those extensive, shattering lesions of bones which open widely into joints, excision of the destroyed bone, though, perhaps, entailing the sacrifice of an articulation, may often leave a limb infinitely more valuable than any artificial substitute; but this is a surgical expedient attended with great danger to life.

Resection or excision is to be substituted for amputation in the following classes of cases: 1. In every injury of the extremities which entails extensive mangling of the tissues, with disorganization of osseous substance, in the child and growing youth. 2. In all cases of compound, comminuted fractures of the phalanges, the carpus and tarsus especially, in the healthy, vigorous subject. 3. In those extensive mechanical lesions of the bone and soft parts, in which doubt remains as to the presence of vitality.

It is well known to experienced surgeons, that children bear the shock of amputation and loss of blood very badly. True, ether anæsthesia stimulates the vital forces for the ordeal and paralyzes the sensory reflexes. But, notwithstanding this, in not a few cases reaction fails to become established and mortal collapse follows.

The Esmarch bandage has contributed somewhat to diminish the loss of blood in amputations for pathological conditions, but in serious traumatisms there is often great loss, and the patient is exsanguinated before assistance arrives. Or, if this has not been so, in the highly vascular tissues of youth, after the amputating-knife has severed the parts and the main blood-trunks have been ligated, the rubber constrictor is slackened, when the blood-wave is let on. Now, if the divided surface be of considerable area, blood oozes from every direction unless cardiac syncope is present; and, in spite of anything that may be done, there may be an irreparable and mortal hemorrhage.

Exclusive of these immediate dangers attendant on juvenile amputations there are other cogent reasons which should serve as an incentive to us to strain our energies in the direction of conservatism. They are, a knowledge of the wonderful recuperative power in children; of the fact that the regenerative energy inherent to their osseous tissues is peculiar to early life, and justifies us often to not only hope for, but promise, results which it would be futile to look for at or after middle life. The preponderance of inorganic elements, their thick vascular periosteal envelope and relatively small quantity of medullary matter, all, in a large measure, explain the *modus operandi* of regeneration in youth.

In extensive disorganizing lesions of the fingers, toes, or body of the hand or foot, no thought of immediate amputation should for a moment be entertained, unless the injury itself has effected the complete destruction of the part, when we complete their severance with scalpel or scissors. But they may be cold and bloodless.

This is no contra-indication to conservative measures; for the temporary frigidity of the parts often arises from shock; when, as the cardiac stroke increases in force, natural warmth returns. Not the smallest portion, then, should be sacrificed in these regions in which it is possible to spare it. Resection here permits us to undermine the soft parts with the rongeur, and detach as much bone as is necessary to secure an ample investment for what remains.

Manual autoplasty by désossement (the unboning of a finger), as practised and taught by Dr. Guermonprez, of Lille, France,[1] must be regarded as one of the greatest triumphs of modern surgery, for by it hands may be made useful and feet spared, which heretofore had to be sacrificed, or, if retained, were useless and unsightly.

In that large group of cases in which we find, immediately after accident or wound, that the circulation has wholly ceased, and we are not certain but the disorganization may be so general that little need be looked for from delay—here, indeed, unless the parts are totally destroyed, we may open through the benumbed, senseless integuments or connective tissues, lift out all free, detached spiculæ and fragments of bone, secure the vessels, place the limb in a comfortable adjustment, and be guided in our final conduct of the case by events which speedily follow after reaction is announced.

Technique of Resection in Traumatisms.—Resection in traumatisms, unlike that in pathological conditions of the bone, is not limited to the osseous tissue alone, but to all that have parted with their vitality. Thus, in the one the rule is to cut away until dense, vascular bone surface is reached; in the other, where there is no diseased, but physically disorganized bone in varying degrees, so much only should be removed as is wholly freed from its periosteal and muscular attachment, which by its presence acts as a foreign substance; besides, such sharp, projecting ends of the shafts as may, by imbedding themselves in soft parts, give rise to irritation and suppuration. The soft parts which have shared in the destruction and are reduced to a pulp, should be stripped away. In a general way I have found the employment of silver wire, in maintaining approximation of the fragments, of little value, necrosis often following its employment, and, when consolidation supervened, more than once the apparent osseous union proved a delusion.

After carefully preserving every remnant of the periosteum possible, deep sutures are inserted, and over fluffy dressings a layer of gypsum is applied. Healing is by granulation, and, as the breach in the parts is left open for the residue of the secretions, no tubing is inserted.

In the healthy, non-contaminated recent wound, no sort of antiseptic solution is employed. Homœoplastic osteoplasty, as taught by Ollier, is of infinite value in many of those shattering, open fractures. The following conditions are necessary for its success: First, with respect to the patient, and next as regards the bone fragment or fragments themselves. The patient must be young and healthy, and be assured perfect quiet for some time following operation. It is indispensable that the bone about to be restored possess the greater part of its periosteal investment, and that there be a contiguity of an ample vascular supply, with a sufficiency of a remaining muscular or connective-tissue attachment.

Where these conditions are present we may hope for coalescence of one or many fragments, and the practical restoration of a shaft or bone. When they are not, then our best efforts at regeneration or restitution will be futile. The re-introduction of a piece of bone completely denuded of its periosteum, bone triturate, or bits of periosteum, in my experience and from what I can learn by personal observation in the practice of others, are of no use whatever. The application of heteroplastic implantation of bone after extensive resection or loss, although many times resorted to, has generally failed; hence many of our ablest and most modern observers seldom mention, except to condemn, it.

The dangers which may follow resection or delay for consecutive amputation, are more theoretical than real in civil life. They are of a description which may be witnessed after any primary amputation.

If effectual hæmostasis be secured, secondary hemorrhage may be always prevented. High inflammatory action may arise, in spite of us, in the syphilitic, tuberculous, or scorbutic, and in malarial districts, if the system be not well fortified by proper constitutional remedies. Septic inflammation may be prevented by the rigid observance of antiseptic or aseptic measures. Tetanus is a rare complication; I have never seen it in this class of cases; nor does it appear that there are any known means to effectually forestall its advent when it is about to invade the system.

Gangrene or mortification in a certain proportion of cases we await. After the lapse of two or three days, according to the activity of the general circulation, gangrenous processes will often, with precision and distinctness, map out the necrotic areas of tissues. When mortification, the complete death of everything is clear, we may then amputate through those parts which have preserved their vitality, and not subject our patient to the dangers of a secondary operation, which may be the case when we cut at an earlier date.

Conclusions.—I. Primary amputation in civil life should never be resorted to in the young, growing subject; nor in the adult, only under very exceptional circumstances; as, when the physical force of violence itself has been so great as to effect total destruction of the part, and the scissors or scalpel is employed to complete the work of division, that the dead may be separated from the living.

II. When a limb or part of a limb must be sacrificed, a consecutive amputation offers the best prospects of survival from shock and a stump less prone to slough, than immediate severance in contiguity of mangled or fatally damaged structures.

III. Resection, in connection with osteoplasty, should be adopted as a general substitute for primary amputation, for by its intelligent and general adoption our patient's prospects are not imperilled, and very much may be saved which has heretofore been sacrificed.

IV. With respect to amputations in general, the ancient doctrine cannot be reiterated with too great emphasis, viz., to sacrifice nothing which may be spared, whether a phalanx metacarpal or metatarsal bone; one of the tarsus or carpus; to spare the joint, no matter how insignificant it may be in function, and never penetrate an articulation if the smallest part of the shaft can be spared.

V. Hot water or solutions of bichloride of mercury should never be employed in resections or amputations through living tissues; for the bone substance is extremely intolerant of either; hence, though the stump promptly closes in, they may have laid the ground-work of an osteomyelitis, which, in the near future, will make a secondary amputation imperative. In those foul, infected tissues, arising from neglect before resection or amputation, and in which we must employ some disinfectant, we should not neglect, after using the corrosive solution, to always follow it by a thorough drenching with pure, sterilized water, with a view of washing away any residue or excess of this powerful irritant that may linger in the wound.

NOTE.—Dr. Manley, after reading his paper, presented seven patients, on whom various operations in the way of resections and conservative surgery, on the upper and lower extremities, had been performed.

[1] Gazette Hebdomadaire de Médecine et de Chirurgie, October, 1891.

Œsipus, the crude fat from which lanoline is extracted, has come into use in dermatology. It is hard and has a bad odor, but the one objection can be overcome by adding sweet oil, and the second by some aromatic.

A TEST REACTION FOR THE CULTURE OF THE MICROCOCCUS PYOGENES AUREUS.

By W. M. L. COPLIN, M.D.,

ADJUNCT PROFESSOR OF HYGIENE AND DEMONSTRATOR OF PATHOLOGY IN THE JEFFERSON MEDICAL COLLEGE; ADJUNCT PROFESSOR OF PATHOLOGY IN THE PHILADELPHIA POLYCLINIC; PATHOLOGIST TO ST. AGNES' HOSPITAL; A. A. SURGEON UNITED STATES MARINE HOSPITAL SERVICE,

AND

D. BEVAN, M.D.,

INSTRUCTOR IN HYGIENE AND IN CLINICAL MICROSCOPY, JEFFERSON MEDICAL COLLEGE.

We have discovered, quite accidentally, that if culture media be made after the following formula, a very definite reaction takes place when inoculated with the micrococcus (staphylococcus) pyogenes aureus. The culture-medium which we have been using in the laboratory for a considerable time in the cultivation of micro-organisms is made as follows:

℞. Meat extract	5 grms.
Peptone, dry (albumin)	10 grms.
Glycerine	62 grms.
Water	1 litre.

To this add agar 1.5 per cent.

Methods for filtering and clearing are the same as in the preparation of other forms of culture-media.

If upon this medium a scratch-culture be made from a growth of the micrococcus pyogenes aureus, it will be found that on the second day after the inoculation the growth of the organism will be manifest; that on the third or fourth day the substratum will begin to become opaque, and by the end of the fifth or sixth day the entire mass of culture-medium will assume very much the appearance of having tapioca intermixed with it. It will be an opaque white, uniform almost throughout the entire medium, except that it will be most dense near the surface, with diminished density as we proceed toward the bottom of the tube. It can readily be proven, by lateral cultures and by cover-glass stains, that the change in appearance is not due to the development of the micro-organism in the deeper layers, but results from some chemical alterations induced, probably, by the microbic alkaloid. So far as we have been able to observe, and we have used the medium for nearly all cultures, the change only takes place in the presence of the micrococcus (staphylococcus) pyogenes aureus and the micrococcus tetragomus, in the latter to a much less degree than in the former. The mixture of several organisms does not seem to change the character of the reaction, so that for the determination of a mixed culture this "pearly white reaction," as it may be called, will be found very significant.

This report may be considered as preliminary in character, as we hope to work out the chemistry of the reaction, and, if possible, find out whether it is an alkaloidal precipitate or a metabolic product.

Laparotomy.—There is at present, says the *British Medical Journal*, a big "boom" in laparotomy in the United States. In New York an "eminent hand" reported two hundred laparotomies performed by himself last year. A country doctor reported thirty-five in one year, and a young doctor in a town of three thousand inhabitants compiled the respectable total of seventy-two in seventeen months. One operator in Detroit thinks nothing of two laparotomies in a day, and lately made a break of three. Rival laparotomists compete with each other, and, if statistics are to be trusted, such hecatombs of ovaries must be offered up on the altar of the New Surgery as might well make American patriots feel some anxiety about the population question. A lady laparotomist has appeared in Michigan in the person of Dr. Florence Huson, of Detroit, who recently operated successfully in a case of ectopic gestation.

The *Journal's* item is, we think, a little belated. It would have been more true three years ago.

A CASE OF TOXIC CENTRAL AMBLYOPIA TERMINATING IN PROGRESSIVE ATROPHY; WITH GENERAL CONSIDERATIONS.[1]

By ALFRED HINDE, M.D.,

SENIOR SURGEON EYE AND EAR DEPARTMENT, CENTRAL FREE DISPENSARY; OPHTHALMOLOGIST TO THE NEUROLOGICAL CLINIC, AND ASSISTANT TO THE CHAIR OF OPHTHALMOLOGY IN RUSH MEDICAL COLLEGE, CHICAGO, ILL.

J. L. G——, aged thirty eight, Canadian, cooper by trade, married, free from venereal infection, has been a beer-drinker to excess for about six years, and would smoke daily from one to two ounces of fine-cut tobacco. During the past two years he has been a great sufferer from dragging pains in different parts of the body. They were "very distressing" in the lower extremities, especially on deep pressure over the posterior surfaces, so that during nine weeks, one year ago, he could not sit down on a chair, and, in order to sleep, he had to rest in the prone position of the body. He had also severe head pains of the same sudden, pulling, steady character. These pains were worse at night, and markedly intensified after each drinking-bout.

During the periods of most intense pain, for two years past, he has been in the habit of relieving, temporarily, his suffering by the internal and local use of alcohol and water. The pains are least severe in warm weather, and during summer time he needed less alcohol than in the winter months.

There is present a marked tenderness on deep pressure over the large nerve-trunks—sciatic and musculo-spiral. He lacks general nervous tone, and his weight five years ago was one hundred and eighty pounds, but now it is about thirty pounds less. He considers that he has been sexually intemperate during the last five years.

About six months since he first noticed that his vision became slightly foggy, and from then until the present this fogginess has become more and more intense, so that now he can see objects somewhat better when not looking directly toward them, or "out of the side of my eye!" With the right eye alone he reads $\frac{12}{cc}$, and with the left only $\frac{1}{cc}$, and glasses do not improve vision. With both eyes he reads only No. X. Snellen at five to seventeen inches. All objects are befogged and must be seen at a nearer point, or at a greater angle—hence of larger size—than is required by eyes having normal vision. The external ocular muscles are healthy, and the intra-ocular muscular apparatus is normal so far as the above range of accommodation is concerned. The pupillary reflexes, direct and consentaneous, are quite torpid, whereas the accommodative[2] reflex is present and much more acute than the others. The pupils are of medium size.

The eyeballs have a healthy appearance and the media are clear. The outer halves of the optic papillæ are much paler than the inner and whiter than normal, and their surfaces are somewhat depressed. The arteries of the retina appear of about normal size and color.

The visual fields are found to contain a central area in which objective vision is markedly impaired but not lost. This scotoma is symmetrically situated in each field, is of oval form, involves the macula, and extends horizontally to the blind spot of the optic nerve entrance. Outside of this central amblyopic region the visual field is more nearly normal, until we reach its periphery. The

[1] Patient shown and paper read before the Rush Medical College Class, at the Neurological Clinic, February 25, 1892.

[2] The impairment of the direct and consentaneous reflexes is most probably due to the anæsthetic condition of the *afferent* optic nerve-portion of the iritic reflex arc, the nuclei of the third nerves and their trunks, the efferent part of the arc, remaining normal. The presence of the accommodative reflex, an associated movement, is most readily accounted for by the fact that the requisite nerve-stimulus for convergence of the eyeballs through the volitional internal recti muscles necessitates a simultaneous explosion from the nuclei of the avolitional sphincter irides and ciliary muscles, because of the interconnection of the three nuclei in the floor of the third ventricle and the aqueduct of Sylvius. These nuclei constitute almost an independent centre with its separate blood-supply, and, together with their branches, as above given are the active mechanism in the production of the Argyll-Robertson pupil wherever found.

right field is peripherically contracted at its upper and nasal limit. The left field is contracted somewhat at its nasal boundary. His color perception is generally impaired—most for greens (appear dark to black), next for reds, then yellows, and least for blues—though he makes mistakes in the grouping of shades of all the above colors.

He has noticed that his vision is worse when the eyes are exposed to a bright light, as on sunny days and at mid-day, more than in the morning and evening, or on cloudy days. He sees very slightly better, on testing, with his back to the light, than when the luminous rays strike the eyeballs.

In ascertaining the history of this patient he first said that he was no whiskey-drinker, and yet, with the peripheral pains, the nerve-trunk tenderness, and the marginal limitation of the visual fields, it was difficult to explain these facts by means of nicotine poisoning alone, and beer had an insufficient amount of alcohol to produce them. Only on further questioning did he admit the ingestion of diluted alcohol as an anodyne.

From the foregoing we are led to a diagnosis of central amblyopia dependent upon a toxæmia due to tobacco and alcohol. The case is a severe or advanced one of tobacco-amblyopia with the added factor of a progressive atrophy, as shown by the extensive involvement of the color sense, and the commencing limitation of the visual fields, together with a peripheral alcoholic neuritis, that preceded the eye symptoms, and continued with them.

The amblyopia due to tobacco is not as much dependent upon the amount of the weed used as upon individual idiosyncrasy. The fine-cut or shag tobacco of the stronger varieties is the most likely to produce the eye-symptoms. Heredity would seem to play a part, for male smokers in a family have been known to be affected, and in these same families some of the women at the climacteric period have been known to develop optic nerve atrophy. Locality and nationality may affect results, for Hutchinson observed that strong tobacco was the controlling drug in these cases in England, whereas, in Germany, Uhthoff [1] found that alcohol played a greater etiological part in the production of "amblyopia."

As might be surmised, the male sex is almost alone in this disease. In Hutchinson's early observations of 69 cases, 4 only were women, and he noticed that persons who learned to smoke with difficulty and those who were especially prone to sea sickness were frequent cases in his group of central amblyopes supposed to be suffering from tobacco-poisoning.

The affected are usually beyond thirty years of age, and rarely have cases been reported in total abstainers [2] from alcohol, and youths have been known to be the subjects of the disease. Again, save in very advanced cases, the evidence in favor of tobacco, as against alcohol, in the causation of the disease, is supported by the fact of the gradual and often complete recovery of such cases on the withdrawal of tobacco, without other treatment.

It is, however, rare to find cases of central amblyopia in smokers who are water drinkers. The large majority are persons who have used tobacco and alcohol to excess and who have lived an otherwise depraved life. Yet, the numerous alcoholic neurotics of this clinic are generally free from dependent eye-symptoms. After years of observation in these cases, and in a few cases of women drinkers, who were not smokers, yet sufferers from general neuritis, I have yet to see the first case of typical central amblyopia.

This would indicate that the connective-tissue inflammation of the optic nerves is much less frequent than inflammation of the same tissue in the spinal nerve-trunks—which accords with clinical observation.

[1] Uhthoff (as quoted by Noyes, Diseases of the Eye, p. 618) in one thousand cases of alcoholismus found six per cent. affected with "amblyopia"; and about thirty per cent. of the one thousand cases had eye symptoms of different kinds.

[2] Among others, Noyes (Diseases of the Eye, 1890, p. 619) reports one case in an artist who "never drank wine nor liquor, but smoked constantly."

In chronic alcoholism the cerebral meninges are markedly thickened from connective-tissue proliferation, and the optic nerve-sheaths are but a prolongation of these, with a reduced blood-supply. Because of the greater distance from the central supply of alcohol, and the relatively smaller blood-supply, and, may be, more complete oxidation of the drug, the less frequent optic viditis may be partially explained. Yet without the alcoholic soaking of the optic nerve tissues, I believe that tobacco alone would as rarely produce interstitial optic neuritis, as much as it fails to inflame the other nerves of the body. Nicotine may have a predilection for the optic nerves, but these cases are most often due to a mixed poisoning.

Again, did we possess the delicacy of exact limitation in the early stage of the spinal neuritis, and know exactly the location in the nerve-trunks of the first-affected fibres, as we do in the optic nerves, there would be little surprise if we learned that the extension of the inflammation spread from the already inflamed sheath first to the outermost fibres of the bundle, as occurs in these optic nerve inflammations.

This probable course would again show the etiological part played by the alcohol, yet we must confess the immunity shown by the comparative rarity of the optic nerve affection, save where tobacco has also been used. The escape of many chronic alcoholics from general neuritis only demonstrates the invulnerability of many persons against the toxic effects of alcohol, a parallel to the chronic smokers who escape a central amblyopia. If the early progress of the two forms of neuritis—special sense and ordinary sensory nerve—should be the same, we can the more easily understand the equally favorable early prognosis in both varieties. Both are peripheral neuritides, and the fact that the optic nerve cannot express a pain, but can only flash a light, is the reason for the principal difference in the treatment of the two forms—one cries for an anodyne, the other does not.

Not considering violet, the color having the smallest area of recognition in the normal retina is that of green; then red, yellow, and blue, in order, have larger fields. The impairment of color-perception, in pathological conditions, is first noticeable for green. If the disease progressively occupies a still larger extent of the nerve or retina, the next color imperfectly recognized would be red, then yellow, and lastly blue.

This general diminution of color-perception, as present in our patient, indicates an extensive involvement of the nerve, and in such a case the optic disk would usually show signs of atrophy, as a rule, occupying its temporal half—also present in our case.

In the early history of central amblyopes, the ophthalmoscopic examination is entirely negative, even the optic papilla has a normal appearance. At this period the pupillary reflexes are usually acute, hence the improvement of vision in such cases is marked where the direct light rays are thrown upon the test types, the eyeballs at the same time being shaded from the intense light. The consequent enlargement of the pupil permits the excitation of a greater area of the retina by the increased number of ethereal vibrations admitted to the interior of the eyeball. The same improvement in vision follows the use of a weak mydriatic solution that affects the sphincter iridis muscle only.

In some cases the acuity of vision is increased temporarily by the inhalation of the fumes of nitrite of amyl to its physiological effect, and it may be used to aid in the rapid, differential diagnosis between cases largely functional and those severer ones where atrophic change has supervened. Increased flow of blood to the optic tissues, from the occipital cortex to the macula, most probably causes the momentary stimulation of the still intact nerve elements.

These much-debated cases are not freed from discussion when their morbid anatomy is considered. The pathology of central amblyopia, as already outlined, is

that of the other toxæmiæ,[1] viz., a peripheral interstitial neuritis. The anatomical explanation for the central scotomata is that of a retro-bulbar affection of the optic nerve fibres that are distributed to the central area of the retina, at first a specifically localized disease of the optic nerves within the orbit. The exact location, in the optic nerves, of the nerve fibres supplied to the macular region, and between the latter and the papilla, and to the peripapillary portion of the retina—the seat of the central scotomata—is in the outermost parts of the optic nerve-trunk next to its sheath. An inflammation of the sheath of the optic nerves with its extension to the connective-tissue partitions, especially of the peripheral temporal portion of the nerves, would readily account for the phenomena of these interesting cases. The diseased portion would include about one-third of the optic nerve fibres, and is most probably at first entirely a functional impairment due to exudative causes, followed at a later period, if the etiological conditions persist, by a pressure atrophy of the nerve fibres, and still later, in some cases, by a progressive inflammation with subsequent atrophy of other portions of the optic nerves.

Some observers have regarded these cases as due to an interstitial neuritis of the axial fibres of the optic nerves. Some consider, and with these we agree, that the fibres of the papillo-macular regions only occupy the central portion of the optic nerves behind the orbit, but that within the latter, and as we approach the eyeball, they lie nearest to the sheath and largely on the temporal side of the nerve; whereas, it is known that the axial fibres within the orbit are spread out in the anterior portions of the retinal expansion, and these parts are not included in the early period of central amblyopia. In our patient, however, they are involved, hence the case has passed beyond a pure one of central scotomata to that of a progressive affection of the optic nerves, and renders the prognosis graver, because of the probability of serious, progressive, and permanent, but not necessarily complete, blindness. In this patient, if we were asked for the immediate anatomical limitation of the disease that would explain the atrophy of the temporal halves of the papillæ, the central scotomata, together with the marginal or peripheral nasal and superior contraction of the visual fields, we would reply that, after the initial inflammation of the optic nerve-sheaths the disease extended especially to the distal temporal portion of the peripheral fibres of the optic nerves, and that the interstitial neuritis, with its base outward and its angle inward toward the centre or axis of the optic nerves, has now reached the axial fibres, and these being affected explain the peripheral contraction of the inner and upper margins of the visual fields; in short, a more or less definitely wedge-shaped neuritis, with its widest part next the temporal portion of the sheath and its apex at the centre of the optic nerve-trunk, and situated immediately behind the eyeballs.

The prognosis in these cases depends upon the chronicity of the disease, the willingness of the patient to entirely forego his bad habits, for many of these cases, as Mackenzie said, "would rather smoke than see," and, we may add, would rather carouse than live. Again, the presence or absence of atrophic signs in the papillæ, or the presence of a marginal scotoma, modifies the future outlook. The prognosis is favorable in first and recent attacks with slight central impairment of vision and when the bad habits are discontinued. When relapses have occurred, there is a possibility of the disease passing into a progressive atrophy with permanent, incomplete, or may be absolute, blindness.

In the early stages of the affection, with simple complaint of a slightly foggy vision, the central scotomata may be overlooked unless great care is exercised in the examination of the visual fields. Even at this period, however, the color-perception is diminished in the area of the scotomata before there is much loss of the acuteness of vision. This is generally the case in all retinal or nerve disease followed by atrophy, and it is an important fact to be remembered in the observation of all such cases, and in doubtful ones the color sense ought to be carefully tested—small color objects being used in preference to large ones. In cases of early simple central scotomata the area of diminished or lost color-perception is sharply defined, whereas in cases of progressive scotomata with atrophy resulting there is a zone of color uncertainty between the lost and normal color fields. Moreover, in the progressive atrophies there is present, sooner or later, marginal and often concentric limitations of the visual fields. Also, in these cases, the temporal halves of the disks are obviously atrophic, as seen by their tendon-like appearance, and their evident depression below the level of the surrounding retina. It must be remembered that the typical central scotoma is always bilateral, and, at the commencement, never an area of lost but only of diminished vision. Paracentral scotomata have also been observed, either together with or independently of the central form.

The etiological indication is our guide to treatment of central amblyopia, and applies to all forms of toxæmic neuritis. To restore the functional integrity of the nerve tissues and to limit further progress of the disease, stop entirely the introduction of both poisons—alcohol and nicotine—into the system, if both are used, or if only one is taken, see that it is interdicted. Restore the normal nervous tone by a carefully regulated life, good hygiene, fresh air, tonics, and a nutritious and easily digestible diet. Iodide of potassium is a useful drug in these cases, especially where active ocular symptoms are present, vision improving, with a reduction of the hyperæmia and irritation. Dry cupping or blistering the temples, together with a guarded general derivation by skin, bowels, and kidneys, is also followed by good results in non-debilitated patients.

For the more chronic cases with apparently permanent blindness, as well as for the general peripheral neuritis, the subcutaneous or internal use of strychnia is advisable. For the spinal neurotic pains the aromatic series of analgesics are to be recommended. Gentle galvanization of the eyes and extremities is followed by good results.

16 Laflin Street.

[1] The uræmic amaurosis, rarely seen, and usually after convulsions in kidney disease, rapidly develops into complete, but usually transient, blindness, has a central origin, and does not require our attention here.

A Matured Infant.—At the session of May 24, 1892, of the Society for Clinical Studies, of Havana, Cuba, Dr. Plá presented a child of three years and ten months of age with an extraordinary abnormal development of the genitalia. When nine months old this child had a continued fever that lasted two months, the temperature oscillating between 39° and 40.5° C. Since then began the abnormal development. To-day his physiognomy is that of an adult, which makes a great contrast with his height, 45 inches; his weight is 60 pounds. The intelligence is below the normal for a child of his age. In regard to the genital organs, the penis, in a flaccid state, measures 4 inches, and when erect, 5 inches; its circumference then is 4¼ inches. He has frequent erections, which are provoked at the least contact, but has no ejaculation. All the pubis is covered with hair. The testicles are unusually large, especially the left one, that measures 3 inches in length by 5 in circumference. The larynx has also an abnormal development, the tone of the voice being *basso profundo* or low base, and the words sometimes do not seem human. Has no hair under the axillæ, but a dark shaded line is shown over the upper lip, formed by very tiny, silky hairs. When one year old he had all his teeth changed, that is, his permanent set of teeth are to day like in a boy fourteen or fifteen years of age.—*Doctors' Weekly.*

A California Quack makes the somewhat rash promise that he will pay half the funeral expenses in cases where he is "not successful."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, July 16, 1892.

NEW CONTRIBUTIONS TO THE PHYSIOLOGY OF THE HEART.

THERE appear to be some practical deductions of high importance which flow from the scientific researches of Dr. C. S. Roy and Mr. J. G. Adami, on the physiology of the mammalian heart. These gentlemen have made a long series of experiments on the organ in question, and have recently presented their results in abstract to the Royal Society. We cannot by any means recapitulate all the facts obtained by them, but will present some of the more important.

The heart usually sends out more blood when it beats slowly, and less when it beats rapidly. This law, if it be one, does not apply however to slowing of the heart from stimulation of the vagus nerve. Slowing from such cause is accompanied by a diminution of the output which may amount to one third. Hence the vagus is a nerve which essentially protects and lightens the work of the heart. It stands in especially close relation with the brain, so that when that organ is flushed and congested the vagus is stimulated and the output of blood lessened. The vagus has a strong inhibitory action on the veins and auricles, but it cannot, however strongly excited, entirely stop the action of the ventricles. In other words, one cannot kill by overstimulating the vagus and stopping the heart. Furthermore, Roy and Adami assert that the action of the vagus on the heart is not a weakening one.

Stimulation of the accelerator or augmenter nerves of the heart increases the output and the rapidity of the beat. In other words, they increase the work of the heart. They do this by increasing the force and frequency of the auricular contractions. It seems, therefore, that both the vagus and the augmenters act upon the heart through modifying the auricular contractions.

There are certain fibres running partly in the vagus which increase, and others which decrease, the activity of the heart when stimulated, acting probably upon the coronary arteries. It is shown that the blood-pressure in these same arteries is an important factor in modifying the activity of the heart, it being increased when they are dilated, and lessened when they are contracted.

It is shown also that the augmenter nerves have no effect on the heart except by inhibiting the vagus; and, conversely, the vagus cannot lessen the strength of the heart's contractions except by acting on the augmenters.

Another very important fact brought out is that a change of the volume of blood in the body affects greatly the contraction volume and output of the heart. Injections into the veins of a volume of defibrinated blood equal to one-tenth of the total blood in the body may double the output. It is important to note, however, that there is no increase in the strength of the ventricular contractions; increase in the work, therefore, of the ventricles due to increase in the output has no tendency to automatically increase the force of the ventricular contractions.

Increase of the watery constituents of the blood increases the contraction volume and output to the same extent (though only temporarily) as does transfusion of blood, but acts more unfavorably on the heart, seeing that the work done by the ventricles is increased, while the nutritive value of the blood supplied to the coronaries is diminished.

It would seem, therefore, that the injection of saline solutions in cases of great cardiac weakness has not a sound physiological basis.

It is shown finally that the change in the heart and circulation which takes place during asphyxia points to the conclusion that, when the total amount of oxygen in the blood is lowered, it is for the benefit of the economy that those organs, such as the central nervous system, whose continuous blood supply is a vital necessity, should be richly furnished with blood by constriction of the vessels of the spleen, kidney, and digestive system, whose blood-supply can be cut off temporarily without danger to life, and also that the heart should carry on the circulation in a manner involving as little waste as possible of its own substance. This it is the function of the vagus nerve to bring about.

HERNIA IN INFANCY.

PREVENTION is better than cure, as all agree, but we fancy that the generality of physicians are not applying this principle to hernia. In an article on "Hernia in Infancy," by Dr. De Garmo, of this city, it is stated that one-half of all abdominal hernias occur during the first five years of life, and we are told later that during this period nearly all hernias could be cured, if properly attended to. The hernias met with in infancy are the inguinal, umbilical, and ventral. Those which are congenital are produced, if inguinal, by the descent of the testicle. Acquired hernias are produced by tight bandaging, constipation with straining, coughing, and in rare cases, from a very tight prepuce. Dr. De Garmo believes that all the hernias of infancy should be promptly and carefully treated. If reducible, as they usually are, they should be replaced and a proper truss with a hard pad worn constantly. All substitutes for trusses such as bandages, elastic bands, hanks of worsted, etc., should be rejected. He says:

"There is no lack of good trusses in this country. The druggists of every town and hamlet in the United States are annually visited by representatives of manufacturers whose products are not equalled in any other part of the world. Furthermore, such patents as were of value have expired, so that competition is in price and quality, resulting to the benefit of the consumer in this instance.

"In selecting a truss for use on an infant the first question is as to the style or pattern which will be best adapted to the purpose. I would condemn all infant trusses which are made to apply from the side of the rupture, all of those where the pad is placed upon a descending arm at a level lower than the pelvic spring, and all trusses cushioned or padded with soft material. The so called French and German styles of truss, which comprise the bulk of stock of many druggists, should have become obsolete half a century ago.

"In making the selection the following points should be borne in mind: First, the spring should be so tempered that it may be readily bent to the exact shape of the child, and its pressure added to or diminished by increasing or removing the amount of curve which it possesses; second, the entire truss should be impervious to moisture, that it may be frequently washed; third, it should be durable.

"The more simple in design the truss is, the better it is, as a rule. Pads with ball-and-socket self-adjusting action, so called, or with complicated set-screws for adjustment, are entirely unnecessary, and soon become useless.

"For the treatment of single inguinal hernia in the infant, the spring which, from the pad, crosses the front of the abdomen, passes around the hip of the opposite side, and across the back, is one of the most valuable appliances that can be used. This truss can be obtained of almost every druggist in the country, the spring covered with either hard rubber or celluloid; it is known in the trade as the "cross-body" truss. A spring of this style will surround about two-thirds of the pelvis, and while it is supplied with a strap to complete the circumference, it readily holds itself in place whether the strap is buttoned or not."

The pressure should be light, and it would be much better if physicians themselves would learn to adjust the trusses and watch them. It is probably in part the patient's fault that this is not done; for he is inclined to save a few dollars by going straight to the instrument-maker.

The truss should be worn for at least a year. In infants under six months of age, the writer seldom uses a truss for the cure of umbilical hernia. The cure is usually accomplished within three or four months, and he employs, as a compress, cork cut so as to press slightly into the navel and support the surrounding parts. Corks used by druggists for wide-mouth bottles answer this purpose exceedingly well. A thin layer of absorbent cotton is placed under this, and the whole is strapped down by one-inch strips of Mead's rubber plaster passing about two-thirds around the body. A dressing of this kind, changed about once a month, we are told, answers every purpose.

However, practically, it is found that the rubber plaster slips or irritates the skin, and if the infant is washed as often as it should be the dressing rarely can be kept on long. In infants Dr. De Garmo finds that an injection of Heaton's fluid helps the cure, though it rarely succeeds with adults.

A Belligerent Parson.—A clergyman in England was recently fined ten dollars for assaulting a physician, one of his parishioners, who had fallen under his displeasure.

GAMBLING FOR THE BENEFIT OF HOSPITALS.

In Paris the authorities have struggled long, and at times earnestly, to suppress gambling, but without success, and they have now learned, what all governments must learn sooner or later, that it is one thing to make laws and another to enforce their observance in the face of public opinion. A nation cannot be made virtuous by enactment, and the conscience of the people must be educated through precept and example, for it can never be quickened through force. So in Paris, having failed to suppress gambling, they have made a virtue of necessity and placed a tax on wagers, turning over the money so obtained to the "Assistance Publique." This body has applied a large portion of the sum thus obtained to the erection of a hospital for consumptives, and smaller amounts have been distributed among other hospitals.

In London there is no such system, we believe, for the Englishman is too virtuous to submit to any tax upon his vices, but many of the hospitals are nevertheless to be benefited this year in a similar way. Baron Hirsch, who is known here chiefly as the rich Englishman who has sent us so many undesirable fellow-citizens, is said to have given the whole of his winnings at the races for the past year to hospitals and other charitable institutions. These winnings amounted to about $35,000, and were distributed to various institutions in sums of from $2,000 to $5,000 each. If all who "play the races" were as liberal as this the hospitals and dispensaries would have few wants unsupplied, and the young practitioner would be in a bad way indeed.

A CONTRIBUTION TO THE CHLOROFORM AND ETHER QUESTION.

An investigation as to the relative danger of ether and chloroform has been conducted by a committee of the German Surgical Congress, and some interesting statistics were given at its recent meeting. Professor Gurlt, the chairman, states that 109,230 narcoses have been observed, of which 39 terminated fatally; of these, 94,123 narcoses were by means of chloroform, the number of deaths being 36—that is, a proportion of 1 to 2,614; ether was employed in 8,431 cases, with 1 death; chloroform and ether, 2,891 times, with 1 death; ether and alcohol, 1,380 times without a fatal termination; bromethyl, 2,179 times, also without deaths; pental, the new remedy, 219 times, with 1 death. Among the chloroform narcoses 836 were by means of Pictet's crystallized chloroform, obtained by the help of intense cold. On the motion of Bruns, the Congress decided to continue the inquiry for another year.

The figures already obtained agree pretty closely with those collected in this country, and abundantly sustain the position long taken by American surgeons as to the relatively greater safety of ether. They also make very incomprehensible the statements of surgeons who, like McGuire, have seen 28,000, or like Nussbaum, 90,000, chloroform narcoses without a death.

Thiophendiodid is the name of a substitute for iodoform brought forward recently by Spiegler of Vienea. It occurs in the form of tubular crystals, soluble in warm alcohol, ether, and chloroform, but insoluble in water.

News of the Week.

A Method of Increasing the Intensity of Heart Sounds.—Azouley (*Gaz. des Hôp.*, May 12, 1892) communicated to the Academy of Medicine of Paris, May 10, 1892, a method of procedure which allows of the more easy detection of cardiac bruits when they are only slightly marked, and which is capable of bringing them into evidence when they are absent during our examination of the patient. It consists in making the patient lie as horizontally as possible, with the arms raised above the head, and the head and legs raised as much as possible on cushions. Cardiac tension is thus increased, and the physical signs accentuated.

Hippocrates on the Mumps.—The genuine works of Hippocrates do not contain a single article devoted especially to diseases in children, and references to children are not numerous. But the paucity in the number of these references is largely compensated for by their interest and the careful description they contain, comparing in some instances closely with the descriptions given in the text-books of to-day. For example, Hippocrates in Book I. of the Epidemics gives the following interesting account of mumps, which shows the wonderful observation of the great master, even in small things: "Swellings appeared about the ears, in many on either side, and in the greatest number on both sides, being unaccompanied by fever, so as not to confine the patient to bed; in all cases they disappeared without giving trouble, neither did any of them come to suppuration, as is common in swellings from other causes. They were of a lax, large, diffused character, without inflammation or pain, and they went away without any critical sign. They seized children, adults, and mostly those who were engaged in the exercise of the palestra and gymnasium, but seldom attacked women. Many had dry coughs without expectoration, and accompanied with hoarseness of voice. In some instances earlier, and in others later, inflammation with pain seized sometimes one of the testicles and sometimes both; some of these cases were attended with fever and some not; the greater part of these were attended with much suffering. In other respects they were free of disease, so as not to require medical assistance." —*Translation of Hippocrates by Francis Adams.*

International Congress of Experimental Psychology.—The second session of the above-named Congress will be held in London, on Monday, August 1, 1892, and the three following days, under the presidency of Professor H. Sidgwick. A Committee of Reception has been formed, which includes among others the following names: Dr. A. Bain, Dr. D. Ferrier, Mr. F. Galton, Dr. Shadworth Hodgson, Professor V. Horsley, Dr. Hughlings Jackson, Dr. Charles Mercier, Professor Croom Robertson, Dr. G. J. Romanes, Mr. Herbert Spencer, Mr. G. F. Stout, Dr. J. Ward, and Dr. De Watteville. Among the papers to be read are the following: Professor Bernheim, on "The Psychical Character of Hysterical Amblyopia;" Dr. Donaldson, on "Laura Bridgman;" Professor Stanley Hall, on "Recent Researches in the Psychology of the Skin;" Professor Horsley, on "The Degree of Localization of Movements and Correlative Sensations;" Professor Lombroso, on "The Sensibility of Women, Normal, Insane, and Criminal;" Professor Richet, on "The Future of Psychology;" Dr. Romanes, on "Facts of Instinct in Relation to Theories of Heredity;" Professor Schäfer, on "The Anatomical and Physiological Relations of the Frontal Lobes;" and Dr. Baron von Schrenk-Notzing, on "A Statistical Study of Susceptibility to Hypnotism."

Hippocrates on the Treatment of Hysteria.—When the uterus fixes itself to the liver. "This happens principally in old maids and widows, or in sterile women, because not giving birth to children they have not the purgation that the lochia would give them. Detach the tumor carefully from the liver with the hand and pull it downward and put a bandage around the hypochondrium. Also use fumigations, purgations, and aromatic fomentations to the uterus. This is only done for widows, but the best cure is pregnancy. For virgins we should recommend marriage; apply nothing to the nostrils; do not even take a purgative; drink, fasting, castoreum and conyza for twenty days in wine which has as much bouquet as possible; avoid anointing the head with any perfume, and do not even smell one." It is evident with Hippocrates it was pregnancy, not sexual intercourse, which was beneficial in the neuroses.

Against Proprietary Medicines.—At the meeting of the Missouri State Medical Association the following resolutions were unanimously adopted:

Whereas, The evil of prescribing and recommending proprietary medicines is constantly increasing, much to the detriment of the profession and the public, especially the latter, many of whom are led into the drug-habit; therefore,

Be it resolved, by the members of the Missouri State Medical Association, That we condemn the practice on the part of some physicians of giving certificates as to the efficacy or special uses and advantages of proprietary medicines, or what is usually understood by this term.

Resolved, That as a body we recommend to the profession the future discontinuance of such medicines, if now used by them.

The Association of Visiting Nurses in Chicago is supported by the society girls of the city, who organize sewing-classes and arrange amateur entertainments, and by professional men and women, who contribute funds for the expenses of the work. Seven trained nurses are employed, and wear a uniform of blue and white, with white collars and cuffs, and a white cross on the left arm. Each nurse has a district in which she goes from house to house among the poor, attending to their sick, and reporting cases of distress to the proper societies for relief. The society has no fund, but is supported by voluntary offerings.

A Biography of Dr. D. Hayes Agnew.—Dr. J. H. Adams, of 252 South Seventeenth Street, Philadelphia, is, at the request of Mrs. D. Hayes Agnew, preparing a biography of her late husband, and is desirous of obtaining from Dr. Agnew's former friends, colleagues, associates, students, and acquaintance all such authentic data as relate in any way to his career or character. Any material, however insignificant, will be welcomed by Dr. Adams, and credit will be given for all facts which are used.

The Summer Corps of Physicians began work on July 5th. There are about fifty of them, and their duty is to visit every tenement-house in the city and to take care of all cases of sickness, especially in children, among the destitute who are unable to pay for a physician's services. They are appointed to serve for two months and are required to devote eight hours each day to the work. The salary is $100 per month.

Dr. Sherman Van Ness, who recently removed to Omaha from this city, has been elected Professor of Gynecology in the Omaha Medical College.

A High Death-rate.—For the twenty-four hours ending at noon on July 12th, there were two hundred and sixty deaths in this city, the largest number of deaths for one day reported in over three years. The large increase was chiefly among children, upon whom the evil effects of hot weather tell with special force.

M. Pasteur is reported to be suffering from "cholerine," a disease which is prevalent now in Paris, and which some believe to be genuine Asiatic cholera.

The Cholera is now declared epidemic in Baku, on the Caspian Sea, and the inhabitants are fleeing from the city, even the government officials and city authorities having deserted their posts. The condition of the sick and of the few who remain to care for them, is said to be deplorable in the extreme. It is rumored that the disease exists in Kertch and other Crimean ports, and Akka, or Acre, on the Mediterranean shore of Asia Minor, is also infected. In Paris, the disease called by the authorities "cholerine," continues to spread, though in a mild form.

Small-pox is prevailing in Victoria, B. C., and all the ports on Puget Sound have established stringent quarantine regulations. Cases of the disease have also been reported in Whatcom and Seattle, in United States territory.

Chicago as a Sanitarium.—A reporter has been interviewing the World's Fair Commissioners as to the probable effect of a cholera epidemic upon the attendance at the great show in 1893. The authorities do not seem to be dismayed at the prospect, and rather affect to believe that Chicago would be a good place to go to to avoid cholera. One of them is reported as saying: "We have one of the healthiest cities in the world. I believe with care we can avoid the cholera." This is cheerful, even if not founded strictly on fact.

Alcoholism.—A Christian Endeavor orator, at the recent meeting in this city, had this to say about alcoholism: "This is, for instance, the golden age of patent medicines; the windows of the apothecary are full of sure cures for drunkenness, and religious and reform newspapers fairly tumble over one another recommending substitutes for regeneration, by hypodermic injections, at a price not one drunkard in three thousand can pay. Drunkenness is sin, not the only one, nor the worst. I would as lief stagger to the gate of heaven drunk and in rags, as a sober, cleanly, dainty, natty hypocrite; I would as willingly roll into judgment limp with alcohol as a calm, clean accomplice of the saloon; I would go as readily maudlin and gibbering to sentence as with the shame-gold of license in my hand, or in my pocket the price of a tenement let to shame. All these are sins, and sinners need at the last diagnosis not salve, but salvation."

New Remedy in Diabetes Mellitus.—Professor Winternitz, of Vienna, recently drew attention to a domestic drug that he thought had been neglected. He related several renal cases that he had successfully treated by an extract made from the wild bilberry. His first experiments with the extract were directed toward the mucous membranes of the mouth, and finding it successful, extended his observations to the bronchi, bladder, and renal organs, where he met with equal success. He admitted having combined with the treatment the hydropathic applications, which were considered to have modified the avowed action and efficacy of the drug. Weil, of Berlin, has now added new testimony to the record of value attributed to this plant, in assuring us that it has acted in a wondrous fashion in apparently curing a young man of diabetes mellitus.

The Library of the American Medical Association is to be moved to Chicago and placed in charge of the Newberry Library.

The Rush Monument Fund amounts now to over $2,000.

A Jenner Centennial will be celebrated in Washington in 1896.

The Annual Receipts of the American Medical Association are $30,468.

Contract Surgeons.—The number of railroad surgeons in this country who practise under contracts is said to be about six thousand. The membership of the Association of Railroad Surgeons has reached about twelve hundred. The objections made to railroad surgeons by their professional brethren are, as stated by a committee of the American Medical Association, first, that under the rules of the railroad companies the railroad surgeon is expected to take charge of all employees and passengers injured in railroad accidents, and this without regard to the ethical rights of any outside physician who may have been called in previous to the arrival of the railroad surgeon. Second, that the railroad surgeon is in the habit of accepting inadequate compensation for his services, which habit is detrimental to the best interests of the profession by lowering the standard of values for surgical services. Practising by contract is being done more every year. Contract practice is not confined to railroad surgeons but includes all the following classes: Medical officers of the Army and Navy and Marine-Hospital Service; medical officers of health, State, county, and municipal; medical officers of public and private hospitals, asylums for the insane, and the deaf, dumb, and blind; physicians to penitentiaries, and jails, and almshouses; physicians to military schools and to schools not military; medical directors to life insurance companies and beneficiary associations; physicians to mines and factories, and furnaces and workshops; and last, the surgeons who practise by contract for the railroads of the country.

The Mississippi Valley Medical Association will hold its eighteenth annual session at Cincinnati, Wednesday, Thursday, and Friday, October 12, 13, and 14, 1892.

Society Reports.

THE CONGRESS OF THE GERMAN SURGICAL SOCIETY.

Twenty first Congress, held in Berlin, June 8, 9, 10, and 11, 1892.

(Special Report to the MEDICAL RECORD.)

In memory of the deceased master of surgery, Bernhard von Langenbeck, the Association of German Surgeons have at last erected a monument, one that could not have been more worthily or imposingly designed; a home for the Surgical Congress, of which the deceased had been President for many years, and finally Honorary President. It was his earnest desire, during his lifetime, to establish an abode, not dependent on time or circumstances, for the Association's work. His wish remained unfulfilled. Now, at last, the name "Langenbeck-haus" will keep alive in the memory of coming generations the name of the noblest and most humanitarian man of our times.

The memorial oration was delivered by the President of the Association, PROFESSOR V. BARDELEBEN; the opening address by PROFESSOR V. BERGMANN. Here were assembled from far and near the friends and pupils of the world renowned master of surgery, to witness this grand celebration. After the dedication of the building, the proceedings for the day were at once taken up.

The Surgical Meaning of New Fire-arms was the title of the first paper, by PROFESSOR BRUNS, of Tübingen. The most important change in the new arms consists in the small calibre of the bullet, by means of which a greater velocity is attained. The velocity is further increased by the new powder. The rotatory movement is also increased. In order to study the effect of the new form of bullets, the speaker had undertaken numerous experiments on living or recently slaughtered animals. From these observations he has arrived at the following conclusions: These gunshot wounds have a different appearance according to whether the bullet comes from a longer or shorter distance. The result is relatively the best at a distance of from 800 to 1,200 metres. At such distances explosions only take place when the cranium is struck. Bones that are struck seldom splinter, but show bullet-openings much more frequently; these even appear on the cranium. The soft parts show at the point of entrance of the bullet a circular opening of 5 millimetres in diameter; at the exit a slit 6 to 7 millimetres in length. Especially at short or very short distances is an explosive action effected, which, although not so considerable as was caused by former arms, is yet sufficiently disagreeable. A shot within close proximity occasions considerable destruction of soft parts and great shattering of bone. On the other hand, there is scarcely anything to be noticed exteriorly. One can hardly imagine what intense shattering has taken place from within from the insignificant point of entrance; this becomes more apparent from the length of the slit at the point of exit. The speaker did not observe bullets remain in a part when shot at a distance of 1,200 metres; on the other hand, shreds and pieces of clothing were not seldom found in the bullet-canal, and in case of bone destruction at the point of bone injury. An important difference between the former lead bullets and the modern Nautel bullet is that the latter does not change its form in entering a part as the former does. Only when it has penetrated a wall or has rebounded against some hard substance is it possible for its shape to be changed, and wounds then become accordingly more dangerous. In consequence of the greater force of percussion, it can be said at present that the degree of mortal injury is proportional to the range of the projectile. Whether, on this account, the number of mortal wounds will be proportionally increased in future wars is questionable. The arms will be held at much greater distances in case of greater danger. At a distance of 100 metres, 4 to 5 ranks of a closed regiment are overcome by the present form of bullet; at 400 metres, 3 to 4 ranks; at 800 metres, 2 to 3 ranks. A change must therefore be made in army tactics, the number of deaths will not then be any larger than in former wars. The new form of arm has, notwithstanding certain disadvantages, special advantages, in that bullet probings and extractions are much less often necessary, and wounds will appear aseptic much more frequently than in former wars. The experience of American physicians during the late Chilian civil war proves this, and shows that the discovery of the new fire-arms is an advance in humanitarian methods. No doubt many complicated questions as to the new form of arm remain still to be solved, as removal of the wounded as quickly as possible from the line to the hospital

The great distances which these arms bring with them add many difficulties; on the other hand, asepsis being possible, and there being a decrease in the danger from hemorrhage, are exceedingly important advantages. In determining the amount of destruction, it is important to remember that this bullet travels in a perfectly straight line from entrance to exit, so that the degree of injury can be calculated from the topography with great accuracy. The speaker recommended the use of a perfectly antiseptic dressing as the first indication in the treatment of such wounds.

In the discussion of this subject DR. REYN, of Hanover, spoke regarding the hydraulic pressure upon organs previously filled with fluid and then shot at. After having performed difficult experiments and calculations, the speaker came to the conclusion that the percentage of mortal wounds is so much less the smaller the calibre of the bullet. He did not agree with the previous speaker regarding the demolishing effect of bullets fired from short distances.

DR. MESSNER, of Munich, had experimented on the question whether the heat developed by such bullets was sufficient to destroy germs placed in their way. For this purpose the speaker shot through boxes containing gelatine cultures, and found that if the bullet passed through cultures consisting of staphylococcus pyogenes or the bacterium of germ pus, such germs developed regularly in the bullet canal.

PROFESSOR HELFERICH, of Greifswald, presented specimens showing extraordinary bone destruction, resulting from firing of bullets of small calibre at shorter distances (about 400 metres).

PROFESSOR KÖNIG, of Göttingen, had observed similar results at greater distances (800 metres).

Location of Field Hospitals.—DR. HAASE, of Berlin, spoke of the position to be taken by hospital-carriers in future wars. Inasmuch as the new form of bullet has a range of four kilometres. it has become necessary to locate the surgical wound-dressing department four kilometres distant from the line of engagement. The speaker pointed out the fact that, while in the late war the dressing department was 1,700 to 1,800 metres behind the line of engagement, in the future only a distance of about 2,400 to 2,500 would be necessary. The position at which ambulances should halt to remove the wounded from the field should be chosen at about 700 to 1,100 metres distant from one's own, 1,500 to 1,600 metres from the enemy's line. Here, at least, the danger begins to be lessened. The attendants work naturally unprotected under greater risks, this was also the case in the war of 1870. At that time the percentage of loss of field attendants was 6.6 per thousand.

At present the fact must be added, that the guards lie most frequently, in their new gray cloaks, flat on the ground, and this accomplish better results. The ambulances are arranged in four, instead of two divisions as formerly, and thus double their results. There is no reason to fear that the wounded will not be sufficiently cared for in the future. It might be desirable, perhaps, to have electric lights to search the battle-field at night.

Hunting-dogs could also be utilized with benefit during the daytime. The whole *personnel* of the lower sanitary staff of officers of the German army comprises over forty-five thousand men.

The Immediate Treatment of Bullet Wounds.—Dr. Langenbuch, of Berlin, recommended the immediate closing of the wound with sticking-plaster or sewing it up. Other prominent surgeons spoke against this method, among whom were von Esmarch, König, and Trendelenburg. It appeared as if the discussion would become endless, when the senior surgeon, Professor Thiersch, of Leipsic, arose and said "We should leave such wounds *open*, but should *close* the discussion;" which was immediately agreed to.

Presentation of Patients.—The second session was in great measure filled up with demonstrations Dr. Guterbock, of Berlin, showed a case of recovery from empyema after resection of several ribs, and Professor Bramann, of Halle, presented several patients from whom brain tumors had been removed. Some of these had already entirely recovered, others were on the way to recovery.

Professor Czerny, of Heidelberg, remarked that trephining was now practised in the treatment of insane. Of course, recovery could not be anticipated at once; on the other hand, trephining had a great future in these cases, in regulating intracranial blood-pressure.

Professor Knöte, of Marburg, showed a patient in whom resection of the ureter for stenosis had been undertaken. The healthy part of the ureter was sewed into the sinus of the kidney.

After this Dr. Reichel, of Wurzburg, spoke of herniæ of the ureter through the inguinal canal, and Dr. Barth, of Marburg, on the histological changes taking place in the repair of kidney wounds, and the regenerative changes of kidney tissue.

Dr. Olsberg, of Hamburg, then read a paper on "Glicoma of the Kidney."

Actinomycosis.—Dr. Schlange, of Berlin, presented several patients who had recovered from the disease. The prognosis of this disease is, on the whole, good. When the head and neck are affected with it, recovery results usually within several months, being seldom delayed more than a year. In case of lung actinomycosis, recovery is only questionable when the pleura is attacked at several distinct points, and perforation takes place. The prognosis of peritoneal actinomycosis is unfavorable if the retro-peritoneal tissue is infiltrated or pyæmia sets in.

In the discussion, Dr. v. Eirelsberg, of Vienna, spoke of a case of actinomycosis in which recovery took place after the injection of tuberculin.

Tubercular Bone and Joint Disease.—Professor König then spoke on the treatment of bone and joint tuberculosis on the basis of modern investigation. From his experience the speaker came to the conclusion that the first indication in treatment is mechanical (rest, extension, pressure, etc.). As an adjuvant to this method, the injection of iodoform serves a good purpose in many cases. Early resections are to be avoided. When sinuses have formed, or caseation or bony necrosis has taken place, the part must be treated more radically; in severe cases by amputation, in milder forms by resection. The action of iodoform, in the treatment of bone tuberculosis, is only local, and it is therefore necessary to determine and treat every tubercular focus.

The third session was opened by a demonstration by Dr. Thiers, of Colberg, who presented a female patient on whom he had closed a provisional anus after the healing of a syphilitic rectal structure.

Flat-foot.—Professor Trendelenburg, of Bonn, followed with the demonstration of a case of recovered flat-foot. After chiselling through the bones of the leg immediately above the malleoli, the foot was straightened. In this way the arches of the foot are brought into such a position as to be able to bear the weight of the body without deformity. Of importance is the observation of the speaker that patients suffering from flat foot suffer also with profuse perspiration of the feet. The speaker believes there is some connection between these two conditions, and is of the opinion that by pressure on the nervus plantaris reflexly a pathological increase in the perspiration is produced.

Pyloric Stenosis.—Professor A. Köhler, of Berlin, showed a patient on whom he had performed with great success a pyloro-plastic operation, according to the method of Heineke-Mikulicz, for pyloric stenosis. The patient, who came to the Charité weighing forty-eight pounds, now weighs one hundred and thirteen pounds. Digestion is again perfectly normal.

Resection of the Trigeminus.—Dr. Krause, of Altona, related a case on whom a successful resection of the second branch of the trigeminus had been performed. A large part of the skull of the one side was chiselled out and turned down, and the wound was tamponed for five days. The second branch of the trigeminus was then sought for, as it passes out of the foramen rotundum, care being taken not to injure other parts. The nerve appeared thickened and reddened. The patient was relieved of her pain immediately, but whether the cure would be permanent time alone would tell.

Professor Madelung, of Rostock, then reported a case of resection of the third branch of the trigeminus.

Operation for Leprosy.—After Professor Bardenhauer, of Cologne, had presented several cases of resection of the upper and lower jaw, Dr. Cramer, of Wiesbaden, showed a case of leprosy. By incision the nerve plexus of the upper arm was laid bare and the nerve structure appeared to have been softened. In the softened places the lepra bacilli were found in small numbers. The smallest of these nerves was laid aside, and two others split longitudinally and scraped until the softened parts were thoroughly removed. The wound was then closed and healed at once. The arm, which until then had been useless, now recovered its normal functions. Relapse had not occurred.

Aseptic Wound Treatment.—Dr. Neuber, of Kiel, then read a paper on this subject. He pointed to the beneficial influence of moisture on the walls of the operating-room. He thought that the first wound infection was frequently brought about through dust from the walls of the operating-room, and he obviates this by keeping the walls moist. If one proceeds in this way, sterilization of instruments and dressings is not always necessary.

Dr. Schimmelbusch believed in the perfect antiseptic treatment of wounds. The infection through germs floating in the air, he did not think half as dangerous as was usually supposed. Infection is greatest by contact with parts; and an energetic sterilization of instruments, dressings, etc., is always necessary.

Professor Bardeleben agreed, on the whole, with the last speaker, yet he believed that in regard to the degree of antisepsis to be practised, every wound must be considered individually.

Abscess of the Brain.—Dr. Arthur Hartmann, of Berlin, demonstrated an interesting case of brain abscess. A dragoon had fallen from his horse in the last French war; after several years he began to suffer from headache, which gradually became serious. He was sent from one physician to another without relief. After opening and cleaning out of the abscess, he was permanently cured.

Discussion was now opened on Professor König's paper on "Bone and Joint Tuberculosis." In general, the other surgeons agreed with König, but in regard to details there were many differences

Dr. Schleich, of Berlin, pointed out the advantageous influence of fat on tubercular foci. He was forced to this conclusion by the fact that tuberculosis occurs exceptionally in fatty organs.

Dr. Schuchart, of Stettin, then spoke of the transmission of tuberculosis through the sexual organs.

Collective Investigation on Anæsthetics. — Dr. Gurltz, of Berlin, gave his report, collected for the Association, concerning narcotization statistics. During the first year of inquiry but 24,625 reports were sent back; the last year 84,605 were sent, from 62 observers. In the first report there were 6 deaths; in the last, 33. A large number of these deaths are certainly to be counted against other concomitant circumstances. These statistics then show 109,230 narcotizations and 39 deaths. Chloroform has caused by far the most deaths, namely, out of 94,123 narcotizations 36 deaths, that is, 1 to 2,614. There were 8,431 cases of ether narcotization, and 1 death; of narcotization from a mixture of chloroform and ether there were 2,891, with 1 death; from mixture of ether and alcohol, 1 380, without any; and from bromide of ethyl, 2,179, without a single death; 219 pental narcotizations, with 1 death. Out of the chloroform narcotizations, 836 were given with crystallized chloroform prepared by Pictet. This preparation is easily kept, and like pental causes narcosis quickly, and does not cause some of the unpleasant results of chloroform. From the very excellent effects of ether, it is to be highly recommended for general use; it has already gained an excellent reputation in this respect in America and England. Bromide of ethyl can only be used for short narcotizations, about three minutes, and can therefore only be used in dentistry. It has also the disadvantage that it does not cause relaxation of muscles.

Professor Bruns, of Tübingen, moved that the collection of statistics be carried on for another year.

Extirpation of the Larynx.—Professor Julius Wolff, of Berlin, opened the fourth session with demonstration of a patient on whom a cancerous larynx had been entirely extirpated. This case is remarkable in that the patient, by the aid of an artificially prepared larynx constructed, according to the ideas of Professor Du Bois-Reymond, by the mechanic of the Physiological Institute, was able not only to speak plainly, but even to sing a song, to the great amusement of the assembly.

Extirpation of the Uterus.—Professor Olshausen, of Berlin, demonstrated some cases of total extirpation of the uterus. According to the experience of the speaker this operation deserves to be more frequently practised. Then followed a communication by Dr. Toronk, of Vienna, on "Primary Sarcoma of the Small Intestine," and one by Professor Schieller of Berlin, on "The Use of the Sculptor's Chisel in Bone joint Operations, especially in Tubercular Cases."

The Mannesmann Hammer and Chisel.—Professor Riedel, of Jena, advocated the employment of these instruments. The homely wooden hammer suffers during sterilization, but its light weight, is on the other hand, a great advantage over the metal hammer. The speaker had a hollow metallic hammer constructed of Mannesmann tubes of suitable diameter and proper strength. The open ends were soldered with steel plates, and the rod of the head of the hammer so widened out that the end plates could not be driven into the rod, which was narrowed toward its centre. The whole hammer was nickel plated.

Operation for Pressure Paralysis.—Dr. Urban, of Leipsic, spoke concerning operative procedures necessitated on account of the pressure of the spinal column against the cord. At the injured point a horizontal incision is made through the skin and soft parts until the column is reached; another incision is also made on the other side and parallel with the latter, some distance beyond the injured part; the spinal column is then chiselled out until the upper half, with the skin and muscles lying above it, can be raised upward and the spinal cord can be laid bare. The part which has compressed the cord is now raised with a chisel or some similar instrument, and the parts are again turned back and allowed to heal. In one of Professor Thiersch's cases the operation was followed with success.

Professor Gluck, of Berlin, presented a case of recovered brain abscess, also several cases of muscle, tendon, and nerve plastic.

Pental Narcosis.—Dr. Philipp followed with an address on pental narcosis used in the practice on children. According to the experience of the speaker, the results are excellent, the evil after-effects of chloroform are entirely absent. Children are very bright immediately after the narcosis, begin to play, and only here and there are cases of slight intoxication noticed. The speaker has never noticed unpleasant results.

On the other hand, Dr. Schede, of Hamburg, reported that in a dozen pental narcoses, only in adults, he had noticed asphyxia in one case and syncope in another.

Hypodermic Anæsthesia.—Dr. Schleich, of Berlin, spoke next on hypodermatic anæsthesia and its relation to general narcosis. The speaker brought about local anæsthesia not only by means of cocaine, but also of other solutions (salt solution, sugar solution, and even sterilized water). He recommended that narcotics should be used only when it was impossible to employ local anæsthetics. Notwithstanding the wishes of the President for some one to express himself concerning the statements of the last speaker, none of the members responded.

In conclusion, Dr. Korte, of Berlin, spoke on the surgical treatment of purulent peritonitis, and Dr. Lauenstein, of Hamburg, on the growth of adhesions in the abdomen as cause of severe colic.

Professor König, of Göttingen, was elected President of the next congress. During this congress numerous electrical, surgical, and bacteriological instruments were exhibited in rooms adjoining the main hall.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, April 11, 1892.

Joseph D. Bryant, M.D., Chairman.

Case of Hip joint Disease Cured.—Dr. A. M. Phelps presented several cases, the first being that of a young man who had been cured of hip-joint disease. When he had come to his office, twenty-two months ago, the femur was fixed at an angle of 30°, was also adducted, the limb shortened three-quarters of an inch. A lateral splint was applied, by which the angle of deformity was overcome and the patient was allowed to walk about. At present the limb permitted of motion from a straight line to an angle of flexion at the hip of 50°, and there was limited abduction and adduction. The fixation-splint had been worn nearly twenty two months, which showed that prolonged fixation of a joint would not of itself cause anchylosis. Anchylosis was determined rather by the severity and character of the inflammation within the joint.

In this case there was also some stiffness in the knee but the motion here would also go on increasing.

Total Extirpation of the Scapula for Tumor, the Arm being Retained.—Dr. Phelps presented the patient and the specimen. The tumor, which was nodular and as large as a child's head, had involved the whole of the outer surface of the scapula, was attached to the second rib, filled the axilla, and pressed upon the brachial plexus. The glands were involved. It had first been noticed about three years ago, but had grown rapidly of late. A diagnosis of malignant disease was made by himself, Dr. Bull, and Dr Morris. Dr. Phelps operated in November, 1891, making Langenbeck's incision, taking away the entire scapula with the tumor. There was some sloughing afterward, due to the fact that by the Langenbeck incision the chief sources of blood supply—the posterior and supra-scapular arteries—were divided. This incision was somewhat T-shaped, the cross being above. Dr. Phelps said that if he were to operate again, he would make an U-shaped incision and turn the skin flap upward, thus avoiding interference with the blood-supply

Had he attacked the second rib to which the tumor was attached, and exposed the pleura, doubtless the patient would have collapsed. Fortunately the tumor had proved to be a simple fibroid instead of malignant, which would account for non-recurrence. The man had limited use of the arm.

Statistics showed total extirpation of the scapula in 118 cases; 58 for tumor, 9 for injury and other diseases; in 51 the reasons for operating not being given. Known deaths, 25; age, from eight to seventy years. Langenbeck first performed the operation in 1855. Two cases were recorded in New York, and he understood that Dr. Weir and Dr. Bull had operated, but the cases had not been reported.

In connection with this case Dr. Phelps again called attention to the value of a serrated artery-forceps, which so bruised the bleeding vessel as to save the necessity for immediate application of ligature. This was important where in a bloody operation it should be completed as soon as possible.

Talipes Varo-equinus; Result of Open Incision in a Man Aged Forty one.—The third patient presented by Dr. Phelps was Dr. Hunt, of Ohio, who had at different periods of his life undergone a number of operations for talipes varo-equinus, but with little benefit, until Dr. Phelps made open incision of the soft parts and overcame further resistance to replacement by using a powerful lever. This instrument had often spared him the necessity for resorting to osteotomy.

Dr. R. F. Weir said he had extirpated the scapula in two (three?) cases. As Dr. Phelps had stated, there was danger of suppuration following the Langenbeck incision.

The Chairman said that about five years ago he extirpated in one case all of the scapula except just sufficient to articulate properly with the humerus. Hemorrhage was controlled by pressure on the subclavian by means of a sort of crutch covered with soft material. A vertical incision in the long axis of the scapula met another in the line of the spine, the lower angle of the bone was lifted, the muscles were divided, and the neck of the bone was cut through by means of bone forceps. Vessels were tied. The loss of blood was insignificant The wound healed by first intention, and the man had good use of the arm. The disease was malignant, recurred in the lung on the same side after six or eight months, and the patient died.

Case of Sciatic Neuralgia Due to an Osteo-sarcoma of the Ilium.—Dr. J. P. Tuttle read the history of the case with the object, he said, of eliciting a discussion on the differential diagnosis of myalgia or sciatica, due to intra-pelvic growths. The patient was fifty-four years of age, began to suffer from pain in the region of the sciatic nerve in the fall of 1891. Two years before he had been treated for muscular rheumatism, from which he made a good recovery. When Dr. Tuttle saw him in December, the sciatic pain was so severe that he could not go up and down stairs. He was pale, but otherwise appeared well. No evidence of an organic lesion could be discovered. No thickening could be felt in the pelvis. There was slight elevation of the temperature. It was supposed there was a slight malarial element in connection with rheumatism. Later Dr. Janeway saw the patient, they examined for neoplasm, etc., but nothing new was discovered. Large doses of morphine were required to control the severe pain. Dr. Sachs saw the patient, and the diagnosis remained unchanged The pain extended, the man became weaker, atrophy began to appear in the muscles of the affected parts. In January the man became heavy, sleepy, presented the aspect of typhoid fever, had temperature elevation. In February, the left leg rapidly became paralyzed. About this time Dr. Janeway felt a thickening in the left iliac fossa. Somewhat later, fluctuating swellings appeared about the hip-joint, but aspiration withdrew only blood. The pulse became peculiar, jumping suddenly back and forth between about 72 and 120. At autopsy the crest of the ilium on the left side readily broke off into his hand, the swellings were hæmatomous, the hip-joint was disorganized, although there had during life been no evidence of joint disease. Dr. Heitzman had pronounced the specimen a sarcoma of the ilium.

Dr. Tuttle thought that obscure sciatic neuralgias were due oftener to intra-pelvic growths than was commonly supposed. A peculiarity in this case was the fact that competent diagnosticians had been unable to feel any structural change in the pelvis about a week before the patient's death, although a careful examination had been made. Referring to the muscular atrophy, it was not noticed until two weeks before death, at which time the reaction to the electrical current was normal.

The Chairman referred to two cases of sarcoma of the pelvis, the first of which was characterized by very severe and persistent neuralgia without marked degree of atrophy; the second by persistent severe neuralgia and rapid atrophy in the limb. A tumor was felt.

A Case of Spina Bifida in an Adult; Removal of Tumor; Relief.—Dr. C. A. Powers read the history of the case (see p. 64).

Dr. Weir had treated three cases of spina bifida, all in children. If a person had carried a spina bifida to adult life, most surgeons would, he thought, be inclined to let it alone unless special symptoms arose. In one of the three children he made iodine-glycerine injections with a happy result. The second patient succumbed after a third injection. In one he operated, but leakage took place, with death. To obviate this, he would in another case elevate the pelvis and place the patient on his side or face. He thought operative treatment would grow more favorable. His experience with meningocele had been limited to one case.

Dr. R. W. Amidon said, with regard to the case reported by Dr. Powers, to whom he had sent the patient for operation, that he thought the spina bifida was the sole cause of the nervous condition, which was one of spastic ataxia.

Dr. Kammerer had seen two cases of meningocele operated upon, one of which did well, the other died from leakage of the cerebro-spinal fluid. It seemed to him the wound could be so sutured as to prevent leakage.

A Unique Derangement of the Knee-joint Demanding Surgical Interference.—Dr. R. F. Weir read the paper (see p. 57).

Drs. Gibney, Phelps, The Chairman, Sayre, and others expressed their interest in the paper, which described what to them was a unique condition. Dr. Sayre was glad to have this evidence that not all troubles of the knee were due to tuberculosis.

The Secret of Father Mollinger's Cures.—Father Mollinger, whose supposed miraculous cures created great excitement in Troy Hill, near Pittsburg, a year ago, died in the early part of June. He did not rely upon faith alone, but prescribed drugs and accompanied the prescription with most explicit directions. The druggist who filled most of these prescriptions, in an interview with a reporter, said that "the secret of the Father's success lay in the fact that his patients always followed his instructions to the letter. They had faith in him, and no matter what he told them they did it." There is more in this than the believers in the dead priest's thaumaturgical gifts would perhaps be willing to concede.

The Cow and the Countess.—The late Sir James Simpson, when giving evidence in a celebrated case in which the possible duration of utero-gestation was in question, quoted an authentic instance of its unusual prolongation in a cow, and was at once caught up by the cross examining counsel with a "Tut! tut! Professor Simpson, what has a cow got to do with this case?" To which Professor Simpson replied, with one of his blandest smiles, "A cow, sir, is just as good as a countess for my present purpose."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CHEMISTRY OF URIC ACID AND GRAVEL—THE LORDS' COMMITTEE ON THE METROPOLITAN HOSPITALS—THE FORTHCOMING ELECTION TO THE COUNCIL OF THE COLLEGE OF SURGEONS.

LONDON, June 25, 1892.

SIR WILLIAM ROBERTS has already achieved distinction for his researches in urinary chemistry. It is therefore not surprising that, on being appointed Croonian Lecturer at the College of Physicians, he should have decided to devote his lectures to giving an account of some further original researches made by him in the same fertile field. In commencing his first lecture, he remarked that the morbid phenomena associated with uric acid divided themselves naturally into those which had reference to gravel and calculus, and those which had reference to gout. In the former, uric acid was thrown down in the free state from the urine as concretions in the urinary channels; in the latter it was thrown down (as sodium bi urate) in the interior tissues of the body. In both conditions the precipitated substance acted as a foreign body and caused mechanical injury, and, in regard to gravel and calculus, the whole of the morbid sequences were thus accounted for. In regard to gout, however, uric acid was supposed to play a double part, and it was commonly believed that, besides the local irritation consequent on the precipitation of crystals of sodium bi-urate in the joints and elsewhere, uric acid in solution in the bodily fluids acted as a true poison. The lecturer intimated that he intended to call in view the soundness of this assumption. He believed it to be more probable that uric acid did not possess any inherent poisonous quality, and that, when mischief did arise from it, that mischief was consequent on the acid being precipitated in the solid form, as sodium bi urate, in the fluids or tissues of the body. That view, if substantiated, would bring gout and uric-acid gravel into closer parallelism. Gout would then become like gravel, in so far as its phenomena depended on uric acid, but of course no further, a disease of which the manifestations were proximately due to mechanical injury.

Sir William Roberts observed that the amorphous urate deposit of human urine formed a convenient starting-point for the study of the pathological chemistry of uric acid. This was the most familiarly known, and perhaps the least understood, of all the urinary deposits. No clear answers were forthcoming as to what was the chemical nature of this substance, and as to what its physiological analogies and pathological relations were. Uric acid was regarded by chemists as a bi basic acid, and, like other bi-basic acids, it formed two regular orders of salts, viz., neutral urates and acid urates, or bi urates. Of late years neutral urates had figured prominently in certain theories of gout, but such theories were untenable on chemical grounds. These urates could only be produced in the presence of caustic alkalies, and in the absence of carbonic acid and the carbonates; but caustic alkalies could not exist in the living organism, and carbonic acid and carbonates were everywhere present, so it seemed impossible that these urates could arise or subsist in the living organism. The acid urates were the most stable salts of uric acid, and tended strongly to assume the crystalline form; they were encountered, pathologically, in gouty concretions, of which sodium bi urate formed the distinctive constituent. The bi-urates did not occur in the unchanged urine, either in health or in disease, and when bi urates were artificially introduced into normal urine they failed to maintain their integrity, and at once underwent a change of composition. Nor was there any actual proof that uric acid ever existed as a true bi-urate in the healthy blood and interstitial juices; there was also evidence that when uric acid was brought into contact with these fluids it was not taken up as a bi-urate. The bi-urates, therefore, though known to us as pathological products in gouty deposits, were not, strictly speaking, known to us as physiological constituents, either in the blood or the urine. Uric acid, however, in some combination or other, did exist normally in minute quantities in healthy blood, and existed in much larger quantities in healthy urine; so the question arose, what was this other form of combination, this normal and physiological combination, which was neither neutral urate nor bi urate, in which uric acid existed in the healthy body? The lecturer proceeded to show that the physiological salts of uric acid were quadri-urates—salts in which the amount of uric acid was double that required to form bi-urates—and described at some length the researches which had led him to this conclusion. His investigations commenced with a chemical examination of the amorphous urate deposit. When mixed with a considerable volume of distilled water this was speedily disintegrated; a portion was precipitated as uric acid, and the remainder passed into solution in combination with the bases as bi-urates. This had been shown by a former Croonian lecturer, Dr. Bence Jones, and he had suggested that a third order of uric-acid salts (quadri-urates) existed. Dr. Bence Jones's research, however, was incomplete, and there were discrepancies in his analyses, probably due to the small amount of material he was able to obtain at once, and to the changes undergone by it on being kept for a short time. On undertaking to reinvestigate this subject, Sir William Roberts said he found that the urinary excretion of birds and serpents, though usually described as consisting of bi urate of ammonia, was really identical with the amorphous urate deposit of human urine. The larger supply of material thus obtainable facilitated analysis, which showed the composition of birds' and serpents' urine to correspond closely with that required with the "quadri-urate" theory. There were differences in the amount of uric acid precipitated by water from the urine of fowls and serpents, respectively, but this was due to the fact that serpents retained their urine for weeks, under which circumstances a certain amount of uric acid was set free.

The lecturer said the study of the amorphous urate, and of the urinary excretion of birds and reptiles, suggested some interesting reflections. These products were substantially identical, and consisted of the quadri-urates of potassium, sodium, and ammonium. In the urine of man and mammals, however, the quadri-urates were only an insignificant item amid a host of other ingredients, while they constituted practically the whole of the urinary excretion of birds and serpents. The kidneys of birds and serpents were anatomically composed of the same structures as the mammalian kidneys, but how widely different was the product of their functional activity! Not merely was there a substitution of uric acid for urea as the final product of nitrogenous metabolism, but there was the strongly contrasted simplicity of the urine of birds and serpents with the complexity of mammalian urine. There was assuredly such a thing as a functional evolution. The anatomical evolution of the kidneys seemed to have reached its term in the lowest vertebrate form; the mammalian kidney presented no essential structural advance, but an immense functional advance had taken place. The results of studying this functional evolution would probably be to show that the evolution of mammalian urine turned mainly on the point that the mammalian plan required that the renal excretion should be voided, not in the solid or semi-solid form, but as a liquid. But why was the problem not solved completely? Why was this small residuum of uric acid left? It might be that the mammalian type had not yet reached its ideal perfection. The residuum of uric acid in mammalian urine might also be regarded as a vestigial feature—as a "memory" of some ancestral form which eliminated its nitrogen as uric acid. The extreme inconstancy of uric acid, both in regard to its presence and its proportion, in

the urine of different species and of different individuals of the same species, agreed perfectly with this theory, for all vestigial structures were conspicuous for their inconstancy, and, like uric acid, though impotent for good, they were sometimes powerful for evil.

Sir William Roberts passed on to the consideration of the state of uric acid in human urine. There was, he said, an inherent tendency in urine to the spontaneous liberation and precipitation of its uric acid. The chemical reactions were interesting to trace out. It was certain that uric acid always subsisted in the unchanged urine as a quadri-urate. The urine in which this substance was dissolved was a watery solution which contained a number of salts. The phosphates were the most important in regard to uric acid, and they easily oscillated between the monometallic forms, or superphosphates, and the dimetallic forms. When, as usually, the former preponderated, the urine was acid; when the latter preponderated, the urine was alkaline. In an acid urine we had the quadri-urate existing in the presence of water and of superphosphates, and these conditions insured the ultimate complete liberation of the uric acid. The first step was the splitting up of the quadri-urate by the action of the water of the urine into uric acid and bi-urate. The resulting bi-urate was immediately retransformed in the presence of superphosphate, by a double decomposition, into quadri urate. These alternating reactions went on until all the uric acid was set free. What were the inhibitory ingredients which prevented uric acid from being thrown out daily and elsewhere in the form of gravel? The lecturer believed that the saline constituents and the pigments had such an inhibitory action. When urine was dialyzed, whereby its crystalline ingredients were for the most part removed, it lost to a considerable extent its power of retarding the decomposition of the quadri-urates. As to the coloring matters, the lecturer said he had noted that deeply tinted urates were more slowly decomposed by water than pale-colored urates, and urine which had been deprived of its pigment by filtration through charcoal acted much more rapidly on amorphous urate. He suggested that a deficiency of saline matters in the urine and a scanty amount of pigment were factors in the causation of uric-acid gravel.

The Select Committee of the House of Lords on Metropolitan Hospitals have just issued a further report. They express an unfavorable opinion as to the method of administration adopted in the three endowed hospitals (Guy's, St. Bartholomew's, and St. Thomas's). They think there is a paucity of convalescent homes generally, and of hospital accommodation on the south of the Thames. On the question of special hospitals their opinion seems somewhat uncertain, but is unfavorable to the smaller ones. They speak with regret of the want of co-operation between the various hospitals, but discourage the interference of a government officer through the proposed Central Board, and think such board should not be given any statutory powers to license hospitals. Nurses' overwork receives some attention, and pensions for nurses are spoken of with approval.

There are no fewer than ten candidates for the four seats on the Council of the College of Surgeons.

A Prolific Negress.—A negro woman now living in New York recently gave birth to her twenty-fifth living child. She is about forty-two years of age, and when sixteen was married to the husband with whom she is still living. She was born in Richmond, and resided in Virginia until seven years ago. Among the twenty five children there have been no twins or triplets.

Druggists' Insurance.—An Accident Insurance Company announces that it is prepared to insure druggists against claims for damages on account of mistakes in dispensing medicines. "Why," asks the *American Lancet*, "should not medical men be insured against similar misadventures?"

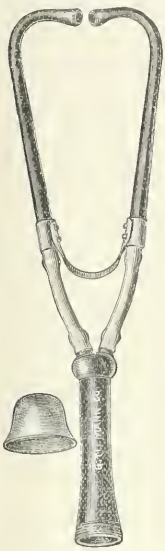
New Instruments.

AN IMPROVED STETHOSCOPE.

By R. K. VALENTINE, M.D.,

BROOKLYN HOME FOR CONSUMPTIVES, BROOKLYN, N. Y.

In presenting this instrument to the profession we claim for it the three cardinal virtues of a stethoscope, namely, excellence as a transmitter of sound; convenience for applying to the chest-wall, and for carrying in the pocket (not an unimportant factor); and thirdly, comparative cheapness. The instrument is composed of hard rubber, the bell and ear-pieces being united by two pieces of ordinary soft-rubber tubing, each about three and a half inches in length.



The bell is a cylinder five inches long, having an internal diameter at the mouth of seven eighths of an inch.

At the top of the cylinder there are two openings, one-quarter of an inch in diameter each, separated by a sharp septum of hard rubber, and the same diameter is continued the full length of the ear-pieces.

When the instrument is in use, the divided waves of sound are carried from the cylinder in two straight lines along the ear-pieces to the curves, which lead them directly into the ears of the operator. The expense of making the stethoscope is largely due to the perfectly smooth finish of the interior of the hard-rubber tubing, throughout its entire length, by which means only are such good results obtained.

A simple method of testing stethoscopes, as to their power of transmitting sound, is by applying their bells to the face of a clock or a watch. By this method the famous instrument of Dr. Dennison, of Colorado—having a diameter of a quarter of an inch more at the mouth of the bell than the one under consideration—is the only stethoscope we have been able to find which transmits a louder sound, and that but slightly, when the accessory bells are not in use; but when this stethoscope is armed with its ordinary soft rubber cone, having a diameter of one and three-quarters inches at the mouth, it transmits a louder sound than does the Dennison instrument even with its largest hard-rubber bell adjusted, and having a diameter of two and three quarters inches. The cause of this is, doubtless, due to the Dennison accessory bell being attached to the permanent bell by passing it within the latter, thus constricting the canal; whereas with this instrument the rubber cone is caught on the outside of the mouth of the cylinder, where several neat circular ridges serve not only for ornament but also for the purpose of retaining it in position.

The ordinary soft-rubber tubing connecting the cylinder and ear-pieces permits of folding, and thus the stethoscope is readily carried in the pocket. Just here we would suggest dropping it into the pocket with the sharply flexed rubber tubing uppermost, so that it will not crease.

When the interior of the bell becomes very dusty, invert the whole instrument under the cold-water faucet, and wash out all the canals.

Thilanine, the new derivative of lanoline by the action of sulphur, is said to be devoid of irritation, and an excellent substitute for Hebra's ointment in many dermatoses. The imported article is now to be obtained in this city.

Contagious Diseases—Weekly Statement—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 9, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	16	8
Scarlet fever	77	7
Cerebro-spinal meningitis	2	5
Measles	270	24
Diphtheria	61	20
Small-pox	2	2
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Surgery in Paris and London.—A correspondent of the *Northwestern Lancet*, writes: "Since writing you last I witnessed several other hysterectomies by Péan, always conducted after the same method, advancing ahead of the knife or scissors with his forceps and applying them upon the broad ligament before severing it. When others would remove only the ovaries, Péan sacrificed the uterus and its appendages, claiming, no doubt with justice, the little value of the organ, the ovaries being gone, and the frequent presence of chronic metritis, as a justification for his procedure. I had the good fortune to witness this operation performed by the veteran L'Abbé, and also by that young and brilliant surgeon, Pozzi, whose latest work on gynecology is known to your readers. L'Abbé's methods have nothing remarkable to notice, but Pozzi advances before the knife with strong ligatures upon the broad ligament. I found in London that the vigorous attention to asepsis observed in France is not by any means followed, instruments being taken from their cases, dipped as a matter of ceremony in the bath, and used without further precaution. At the London Hospital a French physician at my side expressed his surprise, but admitted he had been informed that the English surgeons are no longer observers of surgical cleanliness, and that Lister was the dirtiest of them all. Of the city hospitals I visited, London impressed me as being the richest in material. In one afternoon I found posted for operation two abdominal sections, one sarcoma of the humerus, one popliteal aneurism, one rodent ulcer, and an exploration of the hip-joint. The operation for the relief of the sarcoma was a truly formidable one, consisting of, in the first place, cutting through the clavicle, then tying the subclavian artery, and finally amputating the shoulder, carrying with it all the scapula and its muscles. In London the assistants gather about the patient like house-flies over a speck of carrion, so that absolutely nothing is seen by the supposed spectators, and the method of how not to learn anything is admirably illustrated. In France the internes so conducting themselves would be hissed by the students and quickly brought to time by the surgeons, but in London the seekers after knowledge sit apathetically viewing the house surgeons' backs, and generally desert the amphitheatre after the first surgical procedure. In fact, this thing alone nullifies what practical instruction is given, and served for me as a constant subject of surprise."

The New Rifle-Bullets.—Professor von Bardeleben has been studying the effects of the rifle-bullets used in modern rifles. The new projectile has an inner core of lead, but this is inclosed in a casing of steel, which prevents the lead, even when softened by conversion of motion into heat, from becoming deformed and enlarged at the point of contact with the wound. This change is of much interest for military surgery. The weight of the new 8 millimetre projectile is much less than that of any of the old bullets. It is to its higher rate of velocity and pointed shape that its greater perforating power must be ascribed. Owing to the immense velocity it preserves in its flight, and its small surface of contact, it meets with little resistance on striking a person, causes little commotion of the neighboring parts, has no time to stretch the various tissues it encounters, and merely punches out a hole, carrying the contused elements before it clean out of the wound, without seriously damaging the surrounding wall of the track. The wound is thus left in a fit state for healing by first intention, as no contused parts remain for removal by sloughing. But on the battle-field this absence of contusion, which frequently stayed the bleeding of injured vessels, must lead to more frequent deaths from hemorrhage. Again, in former wars bullets which had been fired from great distances were found to strike the chest or other parts of the body, perhaps to break a bone, and then to glance off or rebound without penetrating farther. This is now impossible; a projectile coming from enormous distances, if it wounds at all, has sufficient power to pass through, cutting any vessels or organs it may meet in it way. Colonel Boonen-Rivera, reporting on the civil war in Chili, where he held the post of Brigade Commander, says that the number of dead on the battle-field was many times—according to his observation four times—larger than that of the wounded. This is the only war in which the new Mannlicher rifles with steel-covered projectiles has been used.

The Barnes Medical College is the name of a new institution lately chartered for the teaching of medicine in St. Louis. Dr. C. H. Hughes, late Professor of Neurology, Psychiatry, and Electro-therapy in the Marion Sims College of Medicine, of St. Louis, is president of the faculty. Dr. Pinckney French, late of the Marion Sims, is secretary. The institution was named after the late Mr. Robert A. Barnes, of St. Louis, who was well known for his many benefactions to charitable and educational institutions. In his will he left more than a million dollars to endow a hospital to bear his name, and to be under the charge and supervision of the Methodist Church.

Rules for the Care of Infants.—The following are the instructions which the summer corps of physicians of the Board of Health distribute throughout the tenement-house districts during their visits. They are printed in English, German, and Italian. "Overfeeding does more harm than anything else; nurse an infant a month or two old, every two or three hours. Nurse an infant of six months and over, five times in twenty-four hours, and no more. If an infant is thirsty, give it pure water, or barley water, no sugar. On the hottest days, a few drops of whiskey may be added to either water or food; the whiskey not to exceed a teaspoonful in twenty-four hours. Boil a teaspoonful of powdered barley (ground in coffee grinder) and one-half pint of water, with a little salt, for fifteen minutes, strain, then mix it with half as much boiled milk, add a lump of white sugar, size of a walnut, and give it lukewarm from a nursing-bottle. Keep bottle and mouthpiece in a bowl of water when not in use, to which a little soda may be added. For infants five or six months old, give half barley water and half boiled milk, with salt and a lump of sugar. For older infants, give more milk than barley water. In hot weather, if blue litmus paper applied to the food turns red the food is too acid, and you must make a fresh mess, or add a small pinch of baking soda. Infants of six months may have beef tea, or beef-soup once a day, by itself, or mixed with other food; and when ten or twelve months old, a crust of bread and a piece of rare beef to suck. No child under two years ought to eat at your table. Give no candies, in fact, nothing that is not contained in these rules, without a doctor's order. Summer complaint comes from overfeeding, and hot and foul air. Keep doors and windows open. Wash your well children with cool water twice a day, or oftener in the hot season. Never neglect loose-

ness of the bowels in an infant; consult the family or dispensary physician at once, and he will give you rules about what it should take and how it should be nursed. Keep your rooms as cool as possible, have them well ventilated, and do not allow any bad smell to come from sinks, garbage-boxes, or gutters about the house where you live. See that your own apartments are right, and complain to the Board of Health, 301 Mott Street, if the neighborhood is offensive. Where an infant is cross and irritable in the hot weather, a trip on the water will do it a great deal of good (ferryboat or steamboat), and may prevent cholera infantum."

It is Proposed to erect a monument to M. de Quatrefages, the well-known French naturalist, whose death occurred recently, and a committee has been formed at Vallerangue, his birthplace, for obtaining subscriptions for this object.

Skatalogical Medicine.—In China pills made from the dung of the Grand Lama of Thibet are used as infallible antidotes to disease. Dr. Mew, of the United States army, recently had the opportunity of analyzing some of them, and he stated that he found "nothing at all remarkable" in them. These sacred pills had been preserved in a silver reliquary, elaborately chased and ornamented, and they came into the possession of Mr. W. W. Rockhill, Secretary of the Legation of the United States in Pekin, through whom they were transmitted to Dr. Mew. Strange as this may seem to those who have not studied the subject, it is not at all remarkable to the ethnologist. Human and animal dung has always been a favorite medicine in some quarters of the world. Such things are never considered disgusting, the Grand Lama offers his excrement to a suffering world as a precious remedy, and the material is provided with great and solemn ceremonies and many prayers. It is not considered by any means a mere excrement, but as a symbolical alvine dejection of miraculous virtue. From the days of Pliny the dung of almost every kind of animal has been used in medicine. Dog dung mixed with honey was prescribed for sore throat, and wolf dung as an anti colic. Goat dung was considered of great value in tumor of the spleen, and cat dung for gout in the feet. Lion dung was an anti epileptic, and mouse dung in the constipation of children. Dr. Jacob Hunerwolf, in 1694, actually wrote a treatise on mouse dung as a laxative, in which he very highly extolled the remedy. Human urine is considered in many places as a most valuable tonic medicine. Daniel Beckherius, in his "Medicus Microcosmus," published in London in 1660, recommends a drink of one's own urine, taken while fasting, for obstruction of the liver and spleen, for dropsy and jaundice. The urine of boys was recommended in fevers, and a "spirit of urine" was distilled for the gout. Boyle, the great philosopher, esteemed human urine so highly as a medicine that he declared that a full account of its virtues would fill a volume. Dr. Neale, in the *Practitioner*, November, 1881, p. 343 *et seq.*, wrote a paper on urine, and compared it with beef-tea and Liebig extract. "Many writers have endeavored to impress the public and the profession with the true value of beef-tea, namely, that it is not a nutrient but a stimulant, and that it mainly contains excrementative materials." Dr. Brown-Séquard's remedy for the invigoration of the aged and debilitated would not be considered at all remarkable by those savage Australians of whom Mr. P. Beveridge tells in his "Aborigines of Victoria and Riverina." Pliny mentions the use of human semen as a medicine, and Avicenna prescribed it for gout. Paullini advises the dirt from soiled stockings as a remedy for epistaxis (p. 52). Dried and powdered afterbirth was used as an anti-epileptic, and secundines were used for the same purpose. The curious investigator of the odd proposals and practice of men of medicine and medicine men will find in Captain Bourke's "Scatological Rites of All Nations" a vast amount of information on this and kindred subjects. He has compiled his great work from one thousand authorities, and though not intended for general perusal, it is one that will interest and inform those at least who consider that the "proper study of mankind is man."—*British Medical Journal.*

Vital Statistics of Total Abstainers.—It is interesting to learn that the annual report of the United Kingdom Temperance and General Provident Institution for 1891 confirms the experience of the previous twenty-five years. In the Temperance Section the expected deaths were 321, and the actual deaths 240, or 70.8 per cent.; in the General Section the expected deaths were 386, and the actual deaths 425, or 110.1 per cent. The total deaths in the twenty-six years in the Temperance Section were 3,663, that is 70.7 per cent. of the 5,177 expected deaths; in the General Section they amounted to 7,934, or 97.5 per cent. of the 7,277 expected deaths.

The Third Intercolonial Medical Congress will be held in Sydney, New South Wales, in September next. The two previous ones were held in Melbourne and Adelaide.

INTESTINAL OBSTRUCTIONS — DIAGNOSIS AND TREATMENT.[1]

BY FREDERICK HOLME WIGGIN, M.D.,

NEW YORK.

ATTENDING SURGEON CITY HOSPITAL, BLACKWELL'S ISLAND; VICE-PRESIDENT LITCHFIELD COUNTY MEDICAL SOCIETY; MEMBER CONNECTICUT STATE MEDICAL SOCIETY; MEMBER NEW YORK COUNTY MEDICAL SOCIETY; VICE-PRESIDENT ALUMNI ASSOCIATION BELLEVUE HOSPITAL; FELLOW NEW YORK ACADEMY OF MEDICINE; MEMBER AMERICAN MEDICAL ASSOCIATION; HONORARY MEMBER GERMAN CONGRESS OF SURGEONS.

MR. PRESIDENT AND FELLOWS OF THE CONNECTICUT MEDICAL SOCIETY: There is perhaps no subject of as much interest to both the physician and surgeon as that of intestinal obstruction. No subject has been more thoroughly discussed, and on none has there been such unanimity of opinion among modern surgical writers as upon the diagnosis and treatment of intestinal obstruction. Had this teaching led surgery to another brilliant triumph over one of her most malignant foes, there would now be no excuse for again travelling so well worn a road. But it is because of her comparative failure that it is timely to again review our knowledge of this subject, and to find out, if possible, the cause of her comparative defeat on what appeared the eve of victory. Are the teachers of surgery wrong in their views? Was Praxagoras wrong, three and a half centuries before Christ, when he advised laparotomy for "the Iliac Passion?" Was the young army surgeon referred to by Bonet wrong when, more than a century ago, in France, he pushed aside the attending physicians, after they had exhausted all the resources of their art, and saved the patient's life by performing the first recorded laparotomy for intussusception? Is the operation *per se* so dangerous? The gynecologists have answered this in the negative. Is the skill of the general surgeon at fault? This may be answered by saying that the most eminent operators have met with failure almost as often as men of less renown. We must look elsewhere for the reason of the comparative failure in this branch of surgery. It is evident from the personal experience of us all, and from a perusal of the journals, that the general practitioner has been too slow in accepting the teachings of modern surgery and in coming to believe that, in urgent cases, medical measures are of no avail, and that the timely operation, as Dr. Jacoby aptly puts it, is the only rational expedient. It is this reluctance to give up the old methods for the new that has too often made laparotomy undertaken for the relief of intestinal obstruction, as a recent writer has said, an "ante-mortem," rather than a "post-mortem, examination." Why is it that Tait, Mann, Polk, Lusk, Cleveland, Price, Kelly, and others in gynecology, and McBurney in appendicitis, are able to report long series of cases with an insignificant mortality, while the general surgeon, with a class of cases which, taken in time, require no graver procedure for their relief, still shows a disheartening mortality? Possibly the report of a few cases taken from the journals of the past year, and some which have come under my own observation, will shed some light on this subject.

CASE I. *Laparotomy for Gall-stones after Five Days' Delay.*—Dr. Barrows reports the following case:[2] Mrs. P——, aged sixty eight, became ill with pain in the abdomen and vomiting; was treated vigorously with purgatives and enemata without result for several days. Vomiting having become stercoraceous, though temperature and pulse were normal, diagnosis of intestinal obstruction was made, and Dr. Barrows called in consultation. Although no nourishment had been retained the same treatment was continued, with addition of the long rectal tube. On the following day the patient seemed slightly better. Slight dulness on percussion, four inches to the left of umbilicus, was found. The next day, patient seeming worse, and not having taken food for five days, operation was proposed and performed. Obstruction was found to be due to a gall-stone three and five-eighths inches in circumference. Death followed six hours later. Says Dr. Barrows: "Had operation been performed when I first saw the case, the termination might have been different. I feel that procrastination was unjustifiable, and proved to be a fatal mistake."

CASE II. *Volvulus Treatment—Long Rectal Tube—Death.*—In a recent journal a writer reports a case of acute intestinal obstruction. Diagnosis of volvulus made early. He remarks: "Case lasted sixteen days, and then patient died of exhaustion after faithful trials of the long rectal tube. The autopsy confirmed my diagnosis."

CASE III. *Volvulus of Small Intestine—Laparotomy after Three Days' Delay—Death.*—Dr. Shafler reports a case[1] of volvulus of the small intestine in a child, aged two, in whom the symptoms of intestinal obstruction were marked for three days. During this time no nourishment was retained. Energetic treatment, consisting of purgative injections of air and water, which added to the patient's misery and produced no result. When the child was thoroughly exhausted laparotomy was performed. Obstruction was found and relieved. The patient died in two hours. "I think," says Dr. Shaffer, "we waited too long, trusting to other means."

CASE IV. *Volvulus of Lower Ileum—Delay—Laparotomy, followed by Death.*—Dr. Pennington reports a case of volvulus of lower part of the ileum.

A young woman, who after severe exercise was taken with severe abdominal pain, vomiting, constipation, tympanites; energetic medical treatment followed, which having failed, and the patient's condition growing rapidly worse, after much delay laparotomy was performed, the patient being so weak that heart failure was feared during the operation. Death followed in eight hours. "The lesson of this case," says Dr. Pennington, "is the unwisdom of delay when urgent symptoms exist. My regret is that we did not operate while patient had the strength to bear it."

CASE V. *Of Intestinal Obstruction—Died from too much Medical Treatment*—Dr. C. H. Dalton,[2] of St. Louis, in a paper read before the American Medical Association in 1891, says: "Surgeons find it difficult to convince the average physician that in a serious case of intestinal obstruction peritonitis can exist with a normal or subnormal temperature." He was called in consultation in a case of intestinal obstruction. He advised operation, but the family physician objected because the patient's temperature was 99½° F. He pointed in vain to the patient's anxious countenance, to the great tenderness on pressure, tympanites, vomiting, and rapid pulse, as well as to the fact that purgatives were of no avail; but the physician insisted on one more dose of salts, and, adds Dr. Dalton, "it was given. It did not

move the bowels, but it did move the patient to that place from which no traveller returns."

CASE VI. *Intussusception — Delay — Laparotomy — Death.*— In a case reported by Dr. B. F. Curtis,[1] the patient arrived at the hospital three days after symptoms which pointed to some grave intestinal trouble had appeared. The diagnosis of acute perforating peritonitis or intussusception was made after patient reached the hospital. Some symptoms pointed to one condition, some to the other. On opening the abdomen an intussusception was found involving eight inches of the ileum, four inches of which was in poor condition and was placed in the abdominal opening. Patient died five hours later, but bowels moved before death. Says Dr. Curtis: "Case showed that adhesions and pathological changes might be slight after intussusception had lasted several days. It also illustrates the need of early operation. Had operation been done twenty-four hours earlier, patient would probably have lived." He also cites another case which proved that a critical collapse might occur so quickly that in a short interval a patient might fall from a favorable to a hopeless condition. "The dilatory course pursued both by surgeon and physician, and especially of the latter, often proves fatal to the patient." The following two cases came under my observation at one of the New York hospitals this winter.

CASE VII. *Intestinal Obstruction due to Strangulation by Diverticulum—Four Days later Laparotomy, and Death.*—A child, aged three, was taken sick November 24th, with the following symptoms: Severe pain, vomiting, high temperature, absolute constipation, and severe prostration. The attending physician was unable to make a diagnosis. On the 28th the child reached the hospital, where a diagnosis of intestinal obstruction was made. On examination no tumor could be found. Temperature in the rectum was 103½° F., marked tympanites. Laparotomy was performed at once. Intestines were found to be constricted by a diverticulum located above the appendix, the free end of which (diverticulum) being adherent to parietal peritoneum, formed a loop through which nearly all the small intestines passed, and had become strangulated. The diverticulum was ligated and removed. The intestines could not be returned. They were incised, and gas and fecal matter allowed to escape. Openings in the intestines were then closed by Lembert sutures. All this added immensely to the length of the operation. Death followed five hours later. This case also teaches the folly of delay.

CASE VIII.—Patient, a male, about thirty-five years of age, was taken sick March 15th, with a severe chill. On the following day localized pain in right iliac region, high temperature, rapid and feeble pulse, persistent vomiting, slight diarrhœa. No diagnosis had been made when the patient reached the hospital on the 19th. On examination diagnosis of appendicitis with perforation was made. Temperature was 105° F.; pulse was 140. The vomiting was arrested by irrigation of the stomach. Laparotomy. On opening peritoneum large amounts of pus welled up. The appendix was removed, but perforation was not found. As patient did not bear anæsthetic well, further search could not be made. The general cavity was irrigated with sterilized water, and wound was packed with iodoform gauze. Hypodermics of strychnia sulphate given. Patient died nine hours later. The four days' delay was fatal to this patient.

CASE IX. *Appendicitis Complicatea by Pregnancy.*—In a case of appendicitis complicated by pregnancy, reported by myself in the MEDICAL RECORD some time since, the patient had marked symptoms of appendicitis, a diagnosis of which was made early. At the request of friends consultations were held morning and night for several days. The diagnosis was not confirmed, because the practitioners were not sure as to the cause of intestinal obstruction, therefore a consent to operation could not be obtained. Perforation and septic peritonitis soon followed. Patient died of exhaustion and sepsis on the fifth day. Autopsy confirmed the diagnosis of perforation, which was caused by fecal concretion. The appendix was not adherent and could readily have been removed. This case again shows the folly of delay, and of the morning and evening consultations, repeated daily for several days, while the patient is rapidly drifting into a condition where operative procedure will be of no avail.

[1] MEDICAL RECORD, October 23, 1891.

CASE X. *Rupture of Ileum—Five Days' Delay—Laparotomy—Death.*—Late on the evening of May 28, 1891, I was called in consultation to see H. W——, aged fourteen, whose physician gave me the following history: On the 23d the boy received a kick in the right lumbar region. The pain, though severe at first, soon passed away. On the evening of the 24th he was suddenly seized with a severe colicky pain, nausea, and vomiting. On the 25th the family physician was sent for. He gave large doses of morphia, magnesia sulphate, enemata, etc., but the constipation was absolute. Finally, as he was losing ground, five days after the accident I was called, and on examination found no external marks of violence. The abdomen was tympanitic, and there was tenderness on pressure at a point two inches to the right of umbilicus. The general abdominal pain had disappeared, vomiting had ceased, constipation was absolute. The temperature was 99½° F.; pulse, 130; respiration, 30. Diagnosis of intestinal rupture and general suppurative peritonitis. Although the prognosis was unfavorable, I advised operation as the patient's only chance. As soon as practicable laparotomy was performed. On opening abdominal cavity the diagnosis was confirmed. A large amount of pus was found in cavity, rupture was closed by Lembert sutures. Abdominal cavity was washed out, first with boiled spring water, and was followed by a weak solution of hydrogen dioxide. Anæsthesia was badly borne. Operation was prolonged by the great intestinal distention, necessitating several incisions to allow gas and fecal matter to escape before they could be returned to the cavity. Could this operation have taken place sooner, the result might have been different.

Diagnosis.—The difficulty is not that the physician cannot decide that there is an acute obstruction, but that the doubt too often arises in his mind of his ability to determine the cause of it, which to him seems of absolute importance, before he is willing to decide on a definite course of action.

The text-books give so many divisions and subdivisions of this subject that this confusion of mind is not to be wondered at, but it too often has been the cause of disaster. If we can show that this refinement of diagnosis is unnecessary, then many of the difficulties which now beset us will have been removed, and many valuable lives be saved. Perhaps this end can be reached by adopting the classification suggested by Bryant,[1] in which cases are grouped by similarity of symptoms and indications for treatment, instead of by causation. This classification is as follows:

1st. Internal strangulated hernia. This includes cases of: *a*, Congenital malformations; *b*, intussusception; *c*, strangulation by bands, diverticula, etc.; *d*, volvulus; and I would add, *e*, some cases of appendicitis.

2d. Cases in which acute symptoms are engrafted on chronic cases, such as: *a*, Cancer of rectum or colon; *b*, syphilitic, tubercular, or simple ulceration.

3d. Cases that cannot be classified, the nature of which is obscure. This includes: *a*, Fecal impaction of cæcum or colon; *b*, cases due to localized peritonitis, the result of injury or extension of inflammation from pelvic or other organs; *c*, cases where operation has been proposed and declined by patient and friends, etc.

Symptoms of Obstruction.—Let us consider the symptoms on which we must depend to make a diagnosis in our first group. They are pain, vomiting, collapse, con-

[1] Lecture on Treatment of Intestinal Obstruction, London *Lancet*, 1891, vol. i., pp. 128–130.

stipation, and tympanites. Given this group of symptoms, we may be sure that we have to do with a case of external or internal strangulated hernia. The former can be excluded from consideration by a careful examination of the usual locations of external hernia.

Differential Diagnosis.—Although it is one of the objects of this paper to demonstrate that the differential diagnosis between members of the first group is of minor importance, it may be remembered that the distinction can frequently be made by a careful consideration of the following individual peculiarities, in addition to those symptoms, common to all, which have been already mentioned. Usually congenital malformations can be detected by examination in the neighborhood of the rectum; intussusception, by the age of the patient, eighty per cent. of all cases occurring in children under twelve years of age; strangulation by bands, diverticula, etc., by the history, which is usually that of previous abdominal inflammation, and by the age, which is that of early adult life. Coe, in a recent number of the *American Journal of Obstetrics*, reports a case of this character, following two days after vaginal hysterectomy. Volvulus, again by the age, which is generally that of advanced life, and by the history, which is that of long continued constipation. Finally, we have to consider acute appendicitis, which is most common in adult males. It begins usually with a chill, followed by rise of temperature; the pains, at first general, afterward becoming localized at or about the base of the appendix.

Second Group Symptoms.—In the second group the symptoms of the obstruction already described are also present. The history and previous rectal examinations will determine the diagnosis.

Third Group Symptoms.—In the third and last group the symptoms of obstruction are present, but in a modified degree.

General Symptoms Common to all Varieties.—Having considered the different forms of the diseases under discussion and their symptoms, we may glance briefly at a few general points which are of interest. In all of these cases the temperature taken per os is a most unreliable guide, being often normal, when at the same time, taken per vaginam or per rectum, it may be much above. In some cases the temperature per os has been normal, while per vaginam or per rectum it was from 103° to 105° F. The respirations are generally increased in frequency; the pulse is rapid and weak, and out of proportion to the temperature as taken per os. The character of the pain is a guide as to the completeness of the obstruction—paroxysmal pain indicating incomplete occlusion; continuous pain, absolute obstruction. Anuria is frequently present, and, according to Treves, is due more to the completeness of the obstruction than to its seat. The seat can be more or less accurately determined as follows: The acute symptoms and early stercoraceous vomiting pointing to small intestine, and chronic symptoms to the large.

Fecal Vomiting not a Reliable Guide.—The attention of the profession has been called to fecal vomiting as a pathognomonic symptom of acute intestinal obstruction, by Dr. McGrow.[1] Says Dr. McGrow: "Fecal vomiting is the only pathognomonic symptom of this condition when taken alone, and an indication that relief or death must soon follow." The objections to depending on this symptom is that it is frequently absent, and in children nearly always, and that if we wait for it to occur before deciding as to what had best be done, relief will come too late.

Differential Diagnosis between Intestinal Obstruction and Enteritis.—The diseases which it has been considered important to differentiate from those we have been discussing are enteritis and peritonitis. Enteritis may be confounded with acute intussusception, but it may usually be distinguished by absence of collapse and elevation of temperature.

[1] See article in Philadelphia Medical News.

Peritonitis.—Much of the doubt and delay which in the past have proved so fatal may be directly charged to the difficulty which the general practitioner has had in trying to distinguish peritonitis from acute obstruction, the one being considered a disease requiring purely medical treatment, and the other demanding what has been regarded as a violent and dangerous procedure. Could it be proved that this distinction is unnecessary, much of the difficulty would be removed. The opinion has become general in Europe, and is rapidly growing here, that acute idiopathic peritonitis is of very rare occurrence. In response to some inquiries I have made, I have received the following letters from two well-known pathologists:

Professor Biggs, of the Bellevue Hospital Medical College, writes: "In reply to your question regarding the frequency of so-called idiopathic peritonitis in my autopsies, I would say that in my experience a primary general peritonitis is exceedingly rare. However, occasionally one does see a case of suppurative peritonitis, in which the most careful search does not show any lesion to which it is secondary. These cases, of course, are microbic in origin, and I think are to be considered analogous to similar primary suppurative inflammations of the pleura, pericardium, and pia mater. The course of entrance of the microbe organisms, and the cause of the localization of the germs in such cases, are often questions involved in great obscurity. Primary infectious inflammation of the other serous membranes are much more common than they are in the peritoneum."

Professor Welch, of the Johns Hopkins University, writes: "I have just received your letter asking for my experience regarding the frequency of occurrence of so-called idiopathic peritonitis. I suppose that you refer especially to acute peritonitis; certain forms of spontaneous chronic peritonitis of a non-tubercular character are familiar to me, but I assume that your question does not refer to them. It is not easy to define sharply just what shall be called idiopathic peritonitis. If the term be limited to cases of acute peritonitis, in which there exists in the peritoneum or other organs or parts of the body no disease which might be assumed to stand in a direct or indirect causative relation to the peritonitis, then acute idiopathic peritonitis is certainly a very rare affection. For the establishment of this variety of peritonitis, clinical observation alone is not sufficient; and even when it seems to be established by a careful post-mortem examination, there is always a possibility that some small primary lesion has been overlooked. This makes it difficult to utilize for statistical purposes the cases of so-called spontaneous or idiopathic peritonitis recorded in literature. Nevertheless, it must be admitted that cases of acute peritonitis occur, in which the most careful examination during life and after death fail to reveal any disease outside of the peritoneum which can be supposed to bear any relation to the peritonitis. I have the notes of an autopsy of this character on a young woman with acute purulent peritonitis. If the epithet idiopathic be applied to all cases of acute peritonitis in which the peritoneal inflammation is the sole manifestation of an infectious process, then it cannot be said that idiopathic peritonitis is extremely infrequent. Any pathological anatomist of experience must have met with cases of acute peritonitis developing in connection with cirrhosis of the liver, or with chronic Bright's disease, without any infectious lesion in the body save the peritonitis. Here we may fairly assume that the presence of ascites, or chronic thickening of the peritoneal membrane, or perhaps of waxy degeneration, acts as a predisposing cause, permitting the growth of pyogenic bacteria which would not have multiplied in a healthy peritoneal sac. If we expand still further the limits, as some writers have done, and designate as idiopathic cases of peritonitis occurring with acute articular rheumatism, with distinct local infections, as for instance tonsillar abscess (I have seen such a case of acute peritonitis), then, of course, the category of

cases is still further increased. I should prefer to limit the term idiopathic peritonitis to the first class of cases. It may be said that there is no *a priori* reason why an acute spontaneous peritonitis of an infectious origin may not occur as well as an acute spontaneous osteomyelitis, for example; but, as a matter of fact, the healthy peritoneum, instead of being, as was once believed, one of the least resistant, is one of the most resistant parts of the body against the lodgement and the multiplication of pyogenic bacteria, as has been abundantly demonstrated by experimental work."

According to the gentlemen whose letters we have read, Osler, Martin and Hare, McBurney, Lydston, and others, the most common form of peritonitis is that due to perforation of the appendix in men, or to rupture of a Fallopian tube in women. There is nothing in the clinical history of diffused suppurative peritonitis, except perhaps the pulse, to indicate the degree of infection. In these cases, as in intestinal obstruction, the pulse is out of proportion to the other symptoms. When a rise of temperature occurs in the course of a case of obstruction, it indicates the existence of peritonitis. Absence of this symptom does not prove its non-existence.

Case of Suppurative Peritonitis without Rise of Temperature.—The following case, reported by Dr. J. N. Sturdy,[1] illustrates this point: The case was one of appendicitis in which the patient died forty-eight hours after the beginning of the attack. The autopsy revealed general peritonitis, pus in the abdominal cavity due to two perforations in the appendix, and yet at no time was the temperature per os over 98½° F. If we accept the opinions quoted above, we may conclude that for clinical purposes we are not warranted in wasting much time in trying to decide whether a severe case is one of peritonitis only, or of acute obstruction complicated by peritonitis.

Treatment.—If I have made clear my own views as to the diagnosis in this class of cases, then one of the purposes of this paper has been accomplished, and the indications for treatment for our first group of cases will at once occur to us. We have shown that the symptoms are those of external strangulated hernia, minus the local tumor. Why should the treatment not be the same in one case as in the others? Why should we expect to remove the cause of internal strangulated hernia by the energetic use for hours and days of opium, the long rectal tube, enemata, and purgatives, any more than in the external variety? No cases of obstruction due to a congenital malformation, strangulation by bands, etc., to a volvulus, a perforating appendicitis, recover without operation, and very few of acute intussusception, especially in young children (a large proportion of those that at first recover by spontaneous sloughing dying later).

Having satisfied ourselves, then, that we have a case of internal strangulated hernia with urgent symptoms, whatever its cause, we should proceed as follows: Pain should be relieved with small doses of morphia or phenacetin. Purgatives should in all cases be avoided. The stomach should be washed out with a hot antiseptic solution, one enema only (a large one), under anæsthesia, should be given, the patient being placed in the Sims position, from a fountain syringe, the bag not to be raised over three or four feet in case of children, and six to eight feet in case of adults. This, if it fails to relieve obstruction (intussusception) or proves our diagnosis wrong (fecal impaction), will prove of advantage in clearing out the bowels below the obstruction. The following case illustrates this point:

Case of Intussusception Relieved by Enema under Anæsthesia.—July 9, 1890, I saw in consultation A. H——, male, forty-two years of age, who gave history of constipation, and after a day of unusual hard work (chopping and lifting logs) he was seized with severe remittent pains and persistent vomiting, which continued till I saw him, three days later. On rectal examination a tumor could be made out. Tenesmus was present. Abdomen was tympanitic. Constipation was absolute. Diagnosis of intussusception. The patient was anæsthetized till his muscles were relaxed. He was then placed in the Sims position, with his hips elevated, and a large enema slowly given from a fountain syringe and forcibly retained till patient recovered consciousness, when he complained of a severe pain. After enema was passed, tumor could not be felt through the rectum. In a few hours bowels moved freely, and the attending physician reported his recovery as uneventful. In case the enema produces no result, it should be followed, with the least practicable delay, by laparotomy. If bowels are much distended, they should be incised opposite mesenteric attachment, and fecal matter and gas allowed to escape. This wound should be then closed, and abdominal cavity irrigated with a normal salt (six per cent.) solution, and the abdominal wound closed.

Treatment of Collapse.—If, on being called to a case, we find the patient collapsed, we should delay, and with small doses of morphia, stimulants, and rest, try to rally our patient, till he reaches a condition to bear the operation.

The following case, reported by Dr. McBurney,[1] illustrates this point: On December 5, 1891, R. W——, physician, aged fifty-six, with previous history of constipation and small tumor in right loin, was seized at 2 P.M. with agonizing pains. At 5.30 P.M. this was relieved by morphia. Temperature, 100° F. At 7 P.M. patient complained of constant pain, which was markedly increased by the slightest pressure at a little above the base of the appendix. Temperature was $102\frac{5}{10}$° F. The pulse was weak, and other well-marked symptoms of shock were present. Three hours later his condition was the same. Diagnosis of perforative appendicitis was made, and during the night patient was treated for shock. The next morning his condition had gradually improved, temperature being 101° F., pulse stronger and 86, and operation was successful.

Enterostomy.—If the case is one in which great prostration and delay have been combined, then enterostomy and irrigation only are indicated. This can be done, as advised by Gregg Smith and others, under cocaine anæsthesia or a minimum amount of ether. After the operation, if the patient is exhausted, if the vomiting has been controlled, early feeding and stimulation by mouth can be employed to advantage. Otherwise this should be done by rectum. Of the treatment in the second group, wherein acute attack is engrafted on a chronic case, little need be said. Indication would be for inguinal or lumbar colotomy as soon as acute symptoms develop. In the third group the symptoms are not as urgent, and we may consider a little longer what our course should be. Medical measures here will in some cases relieve our patient, although in others they will only smooth his path to the grave. In cases of fecal impaction, which are the ones most frequently met with, it is wise first to relieve the pain with morphia and atropia. This should be followed by a large enema of hot water. Many cases of subacute appendicitis recover temporarily. Therefore, when called to see such a case, the question will often arise, Shall we operate or trust to medical measures? While no general rule can be laid down, and each case must be studied carefully, and the question decided on its own merits, we may say that if the symptoms do not show signs of yielding after forty-eight hours of medical treatment, or if there is a history of constantly recurring attacks of the same nature, we should operate. We can never know when a mild case may become one of the greatest malignity, and the time for aid be passed. If it is justifiable to open the abdominal cavity for the correction of a uterine displacement, and for other conditions that involve no danger to life and are simply producing discomfort, are we not more than justified in performing the same operation to clear up a diagnosis in a doubtful case? In such a case, if a

[1] MEDICAL RECORD, February, 1892.

[1] MEDICAL RECORD, April 16, 1892.

mechanical cause exists, the danger to life is great. The autopsy too often shows that the patient might have been saved had we had the courage, on recognizing that some grave abdominal trouble existed, to have performed an operation which, in proper hands and at a proper time, involves little danger. Such an operation would enable us to ascertain whether the trouble was due to a remedial cause or to that rare condition, acute idiopathic peritonitis, complicated by intestinal paralysis. Even in that case, the danger would probably be lessened rather than increased by irrigation. Says a recent writer: "We must constantly bear in mind both sides of the shield. There is danger in performing laparotomy for intestinal obstruction, but there is also danger in postponing it until it must be undertaken as a last resort."

Septic Peritonitis.—The question now arises, does the occurrence of septic peritonitis in these cases contraindicate operative interference? Lawson Tait says: "Whenever I find myself in the presence of localized or general peritonitis, whatever may be the cause, I open the abdomen and treat indications furnished by actual inspection. Peritonitis in abdominal cases is in effect a most powerful indication for surgical interference." Treves, Bantock, and Tait report successful cases of abdominal section for acute puerperal peritonitis. Lawford Knaggs[1] reports a case of successful laparotomy for the relief of acute diffused peritonitis following intestinal obstruction.

Osmolonsky, of St. Petersburg, reports thirteen cases operated on for septic peritonitis due to bursting of intra-abdominal abscess or tumors. Three cases died. Mortality was twenty-seven per cent. He says: "Collapse in these cases does not contra-indicate operation, as Eschers, Wylie, and Hall have saved patients operated on in this condition.

Mickulicz[2] reports seventy-four cases operated on for septic peritonitis, and thirty-eight recoveries. Mortality, thirty eight per cent. And Boully[3] reports twelve desperate cases with six recoveries, mortality fifty per cent.

Dr. Robert Abbe stated in a recent meeting of the New York Academy of Medicine that he had operated on three or four cases in which recovery had taken place, notwithstanding the fact that general suppurative peritonitis was present. He employed thorough drainage by means of openings in the loins. Believing it would be of interest to get the results of recent work in this field, I have communicated with a number of distinguished surgeons, asking what their results had been after laparotomy for general septic peritonitis, and their practice as to drainage and irrigation, and their replies are as follows:

Dr. Andrew McCosh, surgeon to the Presbyterian Hospital, New York, writes: "My results after laparotomy for general suppurative peritonitis have been far from brilliant. One case only has recovered out of perhaps ten patients operated on. Still all the cases have been desperate and absolutely hopeless without operation. The last case you heard me describe lived fifteen days and then died. I have drained in about half the cases, and washed out every two hours the peritoneal cavity. The general cavity is shut off in all cases in from twenty-four to seventy-two hours, so that drainage after the second day accomplishes nothing. I have never used hydrogen dioxide in the general cavity."

Dr. Clement Cleveland, surgeon to the Woman's Hospital, New York, writes: "I have never saved a case of general suppurative peritonitis. Have had but few."

Professor Senn, of Chicago, writes: "I have had several cases of general suppurative peritonitis which recovered after laparotomy, flushing, and tubular drainage. The chronic cases usually recover under such treatment."

Professor J. D. Bryant, of Bellevue Hospital, New York, writes: "In cases of general suppurative peritonitis following intestinal obstruction, or gunshot wounds where extravasation of fæces has taken place, my mortality has been one hundred per cent. I have operated on one case only of general suppurative peritonitis due to other causes. I washed him out freely twice daily with bichloride solution one to five thousand. Patient improved for a time; fever disappeared; suppuration became less, although it continued freely to the end; then died, three weeks later, of exhaustion."

Professor Wyeth, of the Mt. Sinai Hospital, writes: "I do not recollect a single case of recovery after operation for well-established general suppurative peritonitis. Have never drained or washed out every hour or two. In perforation of appendix have saved one case, but peritonitis was not yet general. One case of rupture of gall bladder, with general peritonitis just beginning. I sewed the gall-bladder to abdominal incision and drained it; opened abdomen in linea alba half-way between navel and pubis, and drained by tube. Irrigated general cavity with hot Thiersch solution. Patient recovered. One case of obstruction due to appendicitis with abscess. Opened gut, made artificial anus above obstruction. Opened abscess per vaginam. Closed artificial anus two weeks later. Patient got well and is well, three years afterward."

As the case of appendicitis referred to illustrates the advantage of prompt surgical aid in these cases, I will briefly give its main points. Dr. Baruch[2] says: "Mrs. R. S—— was taken sick twenty-four hours before I was called, having previously been treated for peritonitis by salts and morphia; the temperature was 100° F. Tenderness (exquisite) in right iliac region. Diagnosis of perforating appendicitis was made. I urged sending for a surgeon, but the last train had departed. I insisted on a special train, and Dr. Wyeth arrived at 11 P.M. Peritoneum was opened, and digital examination for adhesions caused a gush of pus. Elongated inflamed appendix was found containing a fecal concretion. Appendix was perforated. This was removed, the general cavity washed and drained, and the wound packed. Pulse, respiration, and temperature fell within an hour. Patient made a rapid recovery."

Dr. J. William White, of Philadelphia, writes: "My experience in laparotomy for general suppurative peritonitis has been, as a general rule, very unsatisfactory. In most instances the cases I have operated upon have been consecutive to rupture of the appendix, or to a rupture of a pyosalpinx, and in the majority of them I have been called in when the patient had septic paresis of the intestines, a swollen and distended abdomen, and evidences of profound shock and general sepsis. I have not time to refer to my notes, but I am under the impression that no less than ninety per cent. of such cases have resulted fatally. The results, however, when peristalsis is still good and the belly is flat, and shock is moderate or absent, have been good; I have found that irrigation at the time of the laparotomy, drainage by tube, and syphonage have appeared to meet all the indications. I have only rarely washed out the abdomen through the tube, nor do I believe it to be of much value, as adhesions form so rapidly that a general irrigation becomes impossible within a few hours after the laparotomy is completed. I have never used the peroxide of hydrogen in the general abdominal cavity in this or in any other case."

Dr. Joseph Price, of Philadelphia, writes: "I have done a large number of abdominal sections for general suppurative peritonitis. My results have been very satisfactory. I mean that I have saved about fifty per cent. of the cases; as they all seemed absolutely hopeless without surgical interference, I feel that the percentage saved is fairly good. Some were puerperal; some followed criminal abortions; others suppurating cysts or dermoids; others due to punctures, and a few to appendicitis, leak-

[2] Ibid.

age or rupture of abscess about the head of the cæcum. My surgery has been rapid and simple. A free incision, free separation of all adherent viscera; even the delicate lymph-adhesions I free rapidly to the exposure of the mesentery on both sides, followed by free douching with pure clean warm water; the flushing and douching always followed by drainage, generally glass, sometimes rubber and gauze. I have a few times done the open treatment with rubber and gauze drainage. The primary douche ends all irrigation. I have never used solutions of any description. I practised the open treatment for purulent peritonitis long before Hebra read his paper on the subject. My practice has been, in the desperate class of cases you are writing about, first to attempt to save life, later, if you save the patient, do ideal surgery. The attendant physician has exhausted all his resources and says to the family, "I have done all I can do," and turns them over at the eleventh hour to us. Surely, the patient is dying, and we cannot do ideal surgery on a dying patient, so I feel it wise to only irrigate and drain. Finish your work later, if you save your patient."

Professor William S. Halsted, of the Johns Hopkins Hospital, Baltimore, Md., writes: "We have cured only two cases of general suppurative peritonitis. Test-tube inoculations were made from the abundant purulent exudation which existed in both cases. In one, the staphylococcus pyogenes aureus, and in the other the bacteria coli, was found. Appendicitis was the cause of the peritonitis in both cases. Both patients died eventually with complications of acute nephritis in one case, and pericarditis, pleuritis, and chronic Bright's in the other. At the autopsies test-tube inoculations were made from the peritoneal cavities, but the tubes remained sterile. There was no exudate from the peritoneal cavity, and except for a slight injection of the peritoneum, there was nothing to indicate that peritonitis had existed in either case. The treatment in both cases was a very thorough washing with a sterilized six-tenths per cent. salt solution. In one case the washing was conducted through two incisions. It is, of course, absurd to attempt to drain the peritoneal cavity, for in a very few minutes the intestines become adherent to whatever is introduced for drainage, and adhering to each other, completely shut off the general peritoneal cavity. To disinfect the peritoneal cavity is also impossible. We have found that irrigation of the peritoneal cavity of dogs with a solution of corrosive sublimate as weak as 1 to 606,000 is fatal. Irrigation with plain water deprives the serosa instantly of its cells, but the so-called physiological salt solution is tolerated very well. You are familiar, of course, with the works of Mikulicz, Reine, and Reichel, and one or two others, who claim that it is better to wipe out the peritoneal cavity than to wash it. I fail to see anything in their experiments which justify such a conclusion in general suppurative peritonitis. The wiping surely offers a greater insult to the serosa than does the irrigation with the salt solution. If the effusion is circumscribed, I can readily believe that it is better to wipe it away than to flood the general cavity."

Dr. M. D. Mann, of Buffalo, writes: "'The existence of purulent peritonitis, however induced, is a clear indication for abdominal section,' says Gregg Smith. This, while generally admitted to be true, has been rarely acted upon on this side of the water. Why should not pus in the abdominal cavity be let out as well as in the pleural cavity? Nor does it make any difference what the origin of the pus may be; pus, if present, must be evacuated before recovery can take place."

I may add, in answer to an inquiry, that Dr. Mann reports one hundred consecutive laparotomies without a death, and in his last two hundred and thirty-six cases he has only had nine deaths, four being due to malignant disease, two to hemorrhage, and three to obstruction of the bowels.

Case of Septic Peritonitis — Operation — Recovery.—The following case is reported by Dr. Zeba H. Evans:[1] Mrs. B——, aged thirty-four, miscarried at three months. Ill one week before Dr. Evans was called; he found patient suffering from puerperal septicæmia; temperature was subnormal and pulse 157. Respirations 34. Marked tympanites and profound collapse. He pronounced her in articulo mortis, which opinion was concurred in by other physicians who were called in consultation, and an unfavorable prognosis was given; but, at the request of friends, it was decided to operate, if the patient could be rallied. Stimulants and milk were administered during the night per rectum, and on the following morning, the patient having rallied, laparotomy was performed. One quart of serum was evacuated. Intestines were not allowed to escape. Free irrigation with plain water till the water escaped colorless. Rubber drainage was employed and the wound closed. Milk was given freely per os during the night. Case did well till the third day, when Dr. Evans was hurriedly called and found the patient with a pulse of 158, temperature 105° F., respiration 33, and patient delirious and picking at the bed clothes. Wound was at once opened and a pint of pus found. Free irrigation with plain warm water. Intestinal adhesions were broken up with the hand. The patient made a complete recovery in five weeks.

While the percentage of recoveries after operations for general septic peritonitis has not been large, still the fact remains that in these desperate cases many recoveries have taken place, and if a case like that given above can be saved, the chance is worth taking in any case, for the operation does not add to the patient's danger. If, unfortunately, we are not called till this complication is added to the previous grave condition, the indications for surgical aid are the more imperative.

Irrigation of Abdominal Cavity.—As to the irrigation of the abdominal cavity, the practice inclines toward the use of plain water or so-called normal salt solution, six-tenths per cent. My own experience and observation lead me to believe that many of the complications following laparotomy can be traced directly to the use of chemical solutions during the operation, either for irrigation, for disinfecting the hands of the operator, his instruments, or sponges. In a case where the abscess is circumscribed, it is bad practice to irrigate, owing to the danger of infecting the general cavity. In all aseptic cases irrigation should be avoided. When irrigation is necessary, while the normal salt solution is best, still in some cases, I believe, this may be followed by a second douche containing a small quantity of hydrogen dioxide. I have used it for several years in all kinds of surgical work, and once in the general abdominal cavity. In a case already alluded to (the patient dying shortly after the operation, no deduction can be drawn from it), and where pus was present, have found it in proper solution more efficient and less irritating than anything else. In some of the New York hospitals, it has been used for irrigating the pleural cavity in empyema, and it has proved satisfactory. I have been unable to find any record of a case where this compound has been used for irrigating the general cavity. In the letters already referred to, Dr. Senn says: "Have used the hydrogen dioxide in cases of limited peritonitis, and should not hesitate to use it in the diffused form."

Dr. Mann says: "And I have never used hydrogen dioxide in the general cavity, but have applied it to the cut ends of tubes, holes in intestines and bladder, etc., with good results."

Dr. Clement Cleveland says: "I have never used the dioxide in the peritoneal cavity. I have used it pure in the uterine cavity, in puerperal septicæmia, with excellent results."

Dr. Robert T. Morris writes: "In localized septic peritonitis, where I have occasion to expose directly the infected locality with retractors, I pour in the H_2O_2 in full strength and without any warming whatever. After allowing it to remain for a minute or two I sponge out

[1] Annals of Gynecology, September 9, 1891, vol. iv., No. 12.

and repeat, leaving the second lot for five minutes, sometimes not removing it at all, but putting my gauze wick down into it and allowing it to be sucked up at leisure by the drainage-wick. I have used it twice only in general septic peritonitis. One of the cases was an appendicitis (perforated), with the patient moribund at the time of application of the H_2O_2, I poured in a very large quantity, enough to bathe all of the abdominal organs; a very little hot water was poured into the peroxide just at the moment of using it, 'to take the chill off.' The peroxide was then siphoned out and the patient was made very much easier by the treatment, although he finally died. The other patient died too. The case was one of general septic peritonitis that had gone on to suppuration after removal of a gangrenous ovarian cyst. The post-mortem examination showed that the H_2O_2 had cleaned the cavity beautifully, and, although my patient died, I nevertheless obtained the impression that one has after such observations, that the H_2O_2 was very useful, and evidently quite harmless in itself. There are lots of cheap peroxides on the market that contain acids, and such would be harmful."

Anastomosis or Enterectomy.—It will often happen, in the course of an operation for obstruction, that we will be obliged to do an anastomosis or enterectomy. At the present time the tendency is to do away with the rings and decalcified bone-plates, etc.

Dr. Abbe[1] says: "Objection to plates in making anastomosis is that the opening is much too small and soon contracts." I believe the future utility of lateral anastomosis lies in making the opening four inches in length in sides of adjacent bowels; this is best done by simple suture."

Dr. W. H. Carmalt,[2] Professor of Surgery, Yale University, reports a case of intestinal obstruction due to cancer of the cæcum, in which he excised (eight inches) and did an end to end union by simple suture (two rows). First two days, patient's temperature ranged between 99° F. and 100.2° F.; pulse, 100 to 110. Third day, temperature, 99.6° F.; pulse, 80. Fourth day, temperature and pulse normal; bowels moved. Sixth day, two stitches were found in the fæces; on eighth day stitches in the abdominal wound were removed and a drop or two of pus being found around it, hydrogen dioxide was used and further trouble avoided. Twelfth day, another stitch was found in fæces, making three in all. Twenty sixth day, the patient was discharged cured.

Dr. Robert F. Weir,[3] of the New York Hospital, reports a case of intestinal anastomosis without rings, between ileum and sigmoid flexure, for intestinal obstruction (neoplasm) in the transverse colon; patient's bowels moved on fifth day, recovery uneventful.

I would like here to call attention to Maunsell's method, which is fully described in the *American Journal of the Medical Sciences* for March, 1892. By this method, circular enterorrhaphy can with a little practice be easily done in ten or fifteen minutes. Since my attention has been called to this method, I have had no opportunity of doing it except on the cadaver, but I have been much impressed with the ease and rapidity with which this operation can be done.

Dr. Hartley, of the New York Hospital, has kindly furnished me with the notes of the following unreported case, in which this method was used. "M. O——, aged twenty-eight. Carcinoma of the sigmoid flexure and double invagination of sigmoid. Presentation of tumor at anal orifice. Intestinal obstruction complete for one week before operation. Laparotomy, reduction of second invagination, and resection of intestines four inches, according to Maunsell's method. Passage of fæces one week after operation. Union by first intention. Temperature never above 100° F. Pulse, 98. Two months have elapsed since operation. Patient is well and has daily movements."

[3] MEDICAL RECORD, April 9, 1892, p. 399.

Conclusion.—And now, in conclusion, a few years ago we had the diseases known as typhlitis, perityphlitis, paratyphlitis, typhilo enteritis, and on being called to a case we waited first to distinguish between the supposed different diseases, then between these and peritonitis, then for the abscess to assume large proportions and make its way to the surface, when it was opened. This was known as the late operation. Occasionally, someone would propose what was known as the early operation. He was generally pointed out as an unsafe man, an enthusiast. At that time the results were much the same, whether the patient was treated medically or surgically. Death ended most cases. But having profited by experience, and largely by that of McBurney, all these so-called different diseases are now grouped under the comprehensive name of appendicitis, the indications for treatment being the same in all. Thus the diagnosis has been simplified, and the time is rapidly coming when the knowledge that a localized peritonitis exists in the region of the appendix, will be sufficient to make us feel it our duty to perform the timely operation which is beginning to produce such good results.

Have we not proved that the responsibility for the frequent failure of surgery in intestinal obstructions rests largely with the general practitioner, through whose hands most of these cases pass on their way to us? May we not do away with much of the doubt and fear which have caused him to hesitate, by grouping those cases in which the symptoms and indications for treatment are the same as has been done in cases of appendicitis? When the general practitioner recognizes that it is only necessary to determine that internal strangulation exists, or that peritonitis is present, before calling in the surgeon, then instead of waiting hours and days, holding frequent consultations in the often vain effort to differentiate the causes of the obstruction, and while so doing using energetically the long rectal tube, cathartics, and repeated enemata, it may not be too much to hope that the timely operation for acute intestinal obstruction will become the rule rather than the exception.

And finally, we may say in the words McBurney has used in another connection, that "if we would accomplish the most by our discussion on this subject, then the surgeon and the physician must join hands, the physician accepting the fact that the surgeon does not always wish to operate, and the surgeon gladly stepping aside when he sees that success can be attained by his colleague's gentler methods."

London Hospitals.—There are nineteen general hospitals in London. Eleven of them have medical schools attached, and three, St. Bartholomew's, St. Thomas's, and Guy's, are endowed. The first of these is the wealthiest and most ancient, having been founded in 1122. Its net revenue in 1889 was $350,000. It owns houses in London and has also about 13,000 acres of land in various counties. St. Thomas's was founded in 1207, and has a revenue of about $220,000. Guy's has a revenue of about $130,000. The London Hospital in Whitechapel Road, with accommodations for 776 patients, is the largest in the metropolis. It treats annually also about one hundred thousand out-patients beside trivial cases not registered. The total number of beds in the general and special hospitals in London is 8,500, of which 6,500 are in constant use. The poor-law infirmaries and the sick wards of the workhouses furnish 14,000 beds, and the Metropolitan Asylum Board has 3,500 for infectious cases, the average number in use being less than 1,000.—*The Sun.*

IMPRESSIONS OF SOME OF THE NEWER DRUGS IN DERMATOLOGICAL PRACTICE.[1]

BY CHARLES W. ALLEN, M.D.,

SURGEON TO THE CITY HOSPITAL, GENITO-URINARY DIVISION, ETC.

THERE is no doubt that many of the novelties of this age are but renovated antiques, still the most firm believer in the adage that there is nothing new under the sun, will scarcely claim that the "new" remedies of the last few years—many of them purely the result of synthesis of logical thought as well as of chemical manipulations—were ever made by mortal man before, or ever used to cure his ills. Never before in the whole history of medicine have remedies been multiplied with such profusion. Before we have had time to familiarize ourselves with the name of the preparation, much less with its supposed virtues, it has, in many instances, been buried in an avalanche of similar remedies for the same purpose—but better—and not always, as one would suppose, introduced by a rival manufacturing firm. Much disappointment is often caused to those who, desiring to use the best, and conscious of the inadequacy of the old, turn to a new remedy which has been lauded by its discoverer, widely advertised by its manufacturer, and whose wonderful effects have been loudly proclaimed by subsidized or deluded journals.

The object of the present communication is to give my impressions of some of the newer remedies for external use, especially in skin diseases, which are not so new but that they have stood the test of time, and to indicate those which the writer has found to possess at least sufficient good qualities to secure for them a place in the list of valuable therapeutic agents.

Naphthol may still be classed among the newer remedies which have not gone to the wall, and while one of the most powerful and safest antiseptics of the phenol series it has not superseded carbolic acid in surgery, as it was at one time thought it might, and still remains a very valuable agent in the treatment of many forms of cutaneous disease.

Five years ago, I believe this very month, I had the privilege of addressing this Society on the subject of Naphthol in Dermatology,[2] and since that time I have continued to employ it in many of the skin affections in which I had till then noted its good effects, and have extended its use to some other conditions. Thus in the parasitic diseases, notably scabies, its action is uniformly favorable, and is increased when combined with sulphur. In pruritic affections, and in pruritus without lesions, it often cures the itching when other remedies have failed. In institution practice I place reliance on an antipruritic oil containing ten per cent. of naphthol. Occasional failures occur, as with any other itch-allaying remedy.

In diseases of the scalp, pityriasis, seborrhœa, seborrhœal eczema, impetiginous eczema, pediculosis, psoriasis, alopecia, and alopecia areata, I may say naphthol has given me as general satisfaction as any other single remedy. I now, more than formerly, combine the bichloride of mercury with it in several of these conditions, and with increased effect. If alopecia is due to any of these diseases, then naphthol tends to check the loss of hair by making the scalp healthy. The stimulating effect upon the healthy scalp has, it seems to me, prevented further loss of hair in many cases, and in some instances has undoubtedly brought about an increased growth. I believe, too, it hastens the natural return of the hair in syphilitic alopecia, as well as that following erysipelas, typhoid, and other debilitating forms of sickness. In women especially, has renewed growth of hair been at times very prompt and satisfactory in the ordinary forms of alopecia. In alopecia areata I have had several recoveries after a course of treatment both surprising to me and gratifying to the patient, by reason of its brevity.

[1] Read before the Manhattan Medical and Surgical Society, May, 1892.

[2] MEDICAL RECORD, May 21, 1887.

In such obstinate diseases as ichthyosis and prurigo of Hebra the results have been very satisfactory; while in milder affections, such as acne, chromophytosis, ringworm, sycosis, etc., naphthol has its use.

A good prescription is:

℞. Naphthol beta ..... gr. xv.
Sulph. prec ..... ʒ j to ʒ ij.
Lanoline ..... ʒ iij.
Cosmoline ..... ad ʒ j.
M.

For scabies the proportion of naphthol can be increased to ten per cent.

The following is the prescription which I have mostly used for the scalp:

℞. Naphthol beta ..... ʒ j. to ʒ ij.
Ol. ricini ..... ʒ ss.
Ol. amygdal. amar ..... ♏ j
Ol. aurantii flor ..... ♏ iv.
Spt. vini. rect ..... ʒ ijss.
M. To be applied to scalp once daily.

In the full strength I have once seen an eczema produced in a scalp the seat of pityriasis.

A practical point in regard to the way ointments should be made. I often see ointments dispensed with the naphthol crystals simply suspended in the base, and this may account for many failures put down to the discredit of the drug. Now, while but slightly soluble in water, it is freely so in alcohol, ether, chloroform, benzole, etc., and it should be ordered to be first dissolved in one of these before mixing with the base, or the druggist will probably neglect it. Perhaps as good a plan as any is that suggested by Hardy, of dissolving in ether, then evaporating the ether with heat before adding the fatty base. I have made extensive use of naphthol soap (two and a half per cent.), with or without sulphur, in parasitic diseases, acne, dry scaly conditions, pityriasis rosea, and pruritus, with often decided benefit. Iodo-naphthol, betol, benzoate of naphthol, and camphorated naphthol, are recently introduced modifications which have not yet come much into use, but the last mentioned compound has already some reputation as an interstitial injection in tuberculous adenitis.

Oxyiodide of Bismuth.—This is a drug which has come into use in certain quarters without the aid of literature. At least I have seen scarcely anything written upon the subject. I think it must be at least five years since my attention was directed to what was then rather a new preparation for wound treatment. It occurs as an insoluble powder of a bright coppery-red color and is without odor. It can be prepared by fusing iodine with bismuth, forming bismuth iodide, and boiling in water, when the subiodide precipitates. Another mode of preparation for small quantities which has been given is by the following formula:

℞. Bismuth subnit ..... ʒ ijss. gr. xxiv.
Acid. nitric ..... ♏ iij.
Aq bul ..... ʒ xij.
M. Dissolve with heat in porcelain capsule, add water slowly, and add

℞. Potass. iod ..... ʒ ix. gr. iij.
Aq. bul ..... ʒ xxviij
M. Add to part first, agitating after each addition, filter, and wash precipitate with boiling water.

So favorable was my impression of this preparation from the first, for the treatment of ulcerative lesions, that I introduced it in three public institutions where up to that time it had not been known, and in spite of its expense it has continued to be much employed and has grown in favor. Although it may be used in the form of an ointment in about ten per cent. strength, my chief experience has been with it as a powder dressing, sprinkled lightly over an ulcer, excoriation, sloughing wound, ulcerating venereal sore, or any other raw surface, it forms a glazed-like covering of metallic lustre which is protective at the same time that it exerts an antiseptic, a some-

what anæsthetic, and a decidedly stimulating and cicatrizing influence, due mainly to the facility with which it gives up its iodine. A thin coating of the powder often appears to produce as good an effect as a larger quantity, and in indolent ulcers, after a liberal use of the powder has stimulated to healthy granulation, the thinner the coat the better. I know of no better powder for the treatment of ulcerating chancre, and it has given me excellent results in balanitis, herpes progenitalis, moist papules about the genitals, condylomata, etc. In strict dermatological cases its action has seemed to me to be rather limited, but as a dressing for moist and ulcerating lesions it appears not inferior to newer and more expensive preparations.

Ichthyol has had so much written about its value that I will refer to it only with a word. I have no hesitancy in stating my belief that in this preparation we have the best known application for erysipelas. I also believe it to be valuable in many cutaneous affections, not only as a reducing agent, but also as an antiseptic. In lichen, acne variioliformis, impetigo, eczema, too much has been claimed for it by over-enthusiastic observers, but no doubt can longer remain that ichthyol is to have something more than the popularity of a day. I gave my views on ichthyol in erysipelas in the *American Journal of the Medical Sciences*, July, 1891, and I can only add that in about a dozen cases treated since then, ichthyol has given uniformly good results.

Resorcin is another of the many new remedies which has weathered the storm. Articles unfavorable to this as well as ichthyol deterred me, in the early days of their introduction, from giving them the extended trial I otherwise would, but more recently the value of resorcin in epi helioma, sycosis, various forms of eczema, intertrigo, ringworm, acne, rosacea, pityriasis rosea, and various other conditions, has been so manifest that for several years I have been employing it more and more. In several cases of pityriasis rosea cure was effected in a much shorter time than is usually required. It furnishes one of the best known means of cure in seborrhœal eczema, and seborrhœa in its several forms; and is of value in the parasitic diseases, especially tricophytosis and sycosis. In strong application it acts as a caustic, and may be employed as such in the treatment of epithelioma. I have had no successes to report. In pruritus the effect of resorcin is often very marked, and the relief afforded lasts for a number of hours. Unna includes it in his reducing agents. Ravogli has reported a case of dermatitis from its use. Care should be taken that the crystals are dissolved before being rubbed up with the ointment base.

Hydrogen Dioxide has of late attracted considerable attention as a microbe destroyer and disinfectant. For a long time it was sold more particularly as a bleaching agent, and one of its first uses in skin practice was on account of its power to remove pigmentary stains, etc. I have employed it for a number of years in removing from the skin and nails such discolorations as were produced by chrysarobin, pyrogallol, permanganate of potash, sulphur, and more recently the aniline dyes which have begun to play a *rôle* in dermatological practice. One day, at Richfield Springs, I was called to see a gentleman who had "turned black" after a sulphur bath, and by no amount of scrubbing had he succeeded in making himself presentable. He had been using a metallic ointment on the face and hands, and the sulphureted hydrogen of the bath had done the rest. A little peroxide of hydrogen soon removed all discoloration and permitted the young man to rejoin the ladies. In another instance, an actress who had entered the bath without first removing the cosmetic from her face, was forced to call upon me before she could leave her room. A solution of the peroxide soon removed the stains. Wherever there is pus to be destroyed, and especially subcutaneous collections of purulent fluid, we have in this preparation probably the best means of accomplishing our purpose. I have found peroxide of great service in paronychia and other affections of the nails. Even in a case of psoriasis of the nail-bed this remedy did more good than any previously tried, softening the thickened epithelium and causing the psoriatic spots to disappear. As a microbe destroyer it is of decided benefit wherever the seat of the disease can be reached. Unfortunately, in such affections as sycoses, tricophytoses capitis, favus, etc., the microbe has its seat so deeply in the tissues that before the fluid can penetrate to it, the more external tissues are swelled up by the fluid and offer a decided obstacle to further benefit. I have employed the fifteen-volume solution as a local application in comedones with some benefit. The black head is bleached in a measure, and there appears to be, aside from this effect, a decided diminution in the inflammatory condition, and where pus and secretions are present they are oxidized and destroyed. If there is much inflammation of the parts or open lesions are present, the strength of the application may have to be decreased by diluting with water. For the application of the peroxide in ointment, it is better to use the ozonic ether instead of the watery solution, as Richardson has pointed out, because of its mixing more readily with fatty substances. Unna has given the following formula for acne:

℞. Lanoline ..... 10.
Vaseline ..... 20.
Hydrogen peroxide ..... 20–40.

I have recently used an ointment made by adding one part of the ten per cent. ethereal solution now on the market to five parts of vaseline. Such an ointment makes an excellent disinfectant to apply to the surface in scarlet fever. On ulcerations the action of the usually employed "fifteen volume" solution—*i.e.*, such a solution of dioxide in water as will give off when decomposed fifteen times its own volume of oxygen—has seemed to me very beneficial, not only because it destroys by oxidation the pus present, but because it appears to have a direct stimulating effect upon the tissues themselves, an effect which can be increased up to the point of cautery by increasing the strength of the solution. In boils, abscesses, superficial and deep suppurating ulcers, moist, secreting syphilitic patches, ulcers in the throat, and in various other conditions, the peroxide has given excellent results.

Pyrozone is the name given to a fifty per cent solution of hydrogen dioxide in ether (the fifteen-volume solution containing about four per cent.). This, when applied to the healthy cutaneous surface, produces an immediate whitening of the skin which remains for a considerable time, and is attended at first by a slight tingling and occasional sharp twinge of pain, and usually some subsequent itching. If the application is repeated on the same or following day, vesiculation will take place, and this sometimes happens after the first application. I have made use of this new preparation in several instances of chloasma, flat pigmented nævi, and flat warts, with gratifying results. In one case where it was brushed over the surface of a congenital pigment mark the size of a silver dollar, on a lady's neck, the pain was much complained of for fifteen minutes, and from the amount of surrounding erythematous redness it could be seen that a pronounced effect was produced, though blistering did not occur.

Aristol.—Since I made a report on the use of aristol in skin diseases at the meeting of the American Dermatological Association, in September, 1890, I have continued to employ it in a variety of affections, and find it of decided benefit in all cases where a granulation stimulant and cicatrizing agent is required. Its value probably depends upon its richness in iodine, containing as it does something like forty-five per cent. It has the advantage over the newer dermatol in being soluble in oils, ether, and alcohol, though only slightly so in the latter.

At the out-door department of Bellevue I have used aristol extensively in the treatment of chancroid, and,

contrary to the experience of others, and the statements frequently made that it is of no great value in this condition, I must record my experience in favor of it. In lupus, psoriasis, and epithelioma, the action, while it cannot be said to be curative, is highly beneficial. It will remove the lesions of psoriasis, but it does not do the work as quickly and thoroughly as does chrysarobin. I do not believe that a case of epithelioma has been or will be cured by aristol. It may cause cicatrization of an ulcerating cancer, but the disease will be still present. At the last meeting of the American Medical Association, in discussing aristol, Dr. Keller said: "In epithelioma I am convinced its action is admirably curative, often seeming to cure it rapidly and completely." Now, I am afraid such statements are misleading. The drug does just what Dr. Keller says, it seems to cure. If he or anyone else can state instances of permanent cure of epithelioma, I should be much pleased to know it. I have used aristol extensively in epithelioma, but only in the hope of causing cicatrization in cases gone beyond the operative period, and to cause healing of the wound after operation in the other class of cases. I have only words of praise to use for the drug in this sense, but as a cure for cancer I am unfamiliar with it. The same may be said of lupus. Ringworm, eczema marginatum, ulcers, erysipelas, have all appeared to be influenced favorably by aristol dressings. Neisser, however, has found that aristol possesses no antibacterial power on cultures. As an application to mucous membranes, as in the nose, it has given good results, and several cases of syphilis of the nose and ozæna have been much benefited. It is my usual dressing for most of the open lesions of relapsing periods of syphilis. As it is insoluble, wherever a penetrating action is desired, instead of a simple superficial coating of powder, an oily or ethereal solution or ointment should be used.

In closing my previous report on aristol I say: "In dermatological cases it has a certain though limited application." This view I have not yet changed.

Europhen.—This is another iodine product introduced by the same manufacturers as a substitute for iodoform. It contains much less iodine than aristol, only about twenty-seven per cent. Like aristol it is insoluble in water or glycerine, but is dissolved in alcohol, ether, chloroform, and fixed oils, and so like it can be used in collodion, or ointment, preferably with lanoline traumaticine, and is generally employed in from one or two to five per cent. strength. Three per cent. is usually strong enough. It has to me the old familiar smell of iodoform, but much less pronounced. It is not so disagreeable to the nostril as iodoform, but if it is chosen to replace the latter solely on account of the smell, I fear disappointment will at tend its employment. The advantages over iodoform appear to be that it is not toxic. It does not tend to harden, pack, or mass into lumps as iodoform so often does. A much smaller quantity suffices to cover a given diseased surface, as it is five times as light as iodoform. It adheres, in other words, more closely to denuded surfaces than does iodoform, but this is true of dermatol, aristol, and subiodide of bismuth. The odor is said to resemble saffron. Its action in chancroid surpasses that of aristol.

A faulty translation in the *Sanitarian*, October, 1891, makes Eichhoff state that it is efficacious in psoriasis and favus; this has been copied into many other journals, and the error has been propagated. Eichhoff distinctly states that these diseases are not benefited. I have not thought it worth while to try it in psoriasis, but a short trial in favus convinced me that it was not of much value. The literature would indicate that up to now europhen had found its most important field of usefulness in nose and throat work.

Like aristol, its use in cutaneous diseases must remain restricted. In some comparative clinical experiments between dermatol and europhen on the one hand, and between them and other plans of treatment, I found europhen inferior to dermatol, both inferior to aristol, but all less valuable than older remedies in a variety of affections, especially impetigo, impetigo contagiosa, chancroidal and other ulcerations.

Dermatol is the name given to one of the most recently introduced substitutes for iodoform. It occurs as a fine yellow, non hygroscopic powder, odorless, non-poisonous, and non irritating. It is formed by a combination of gallic acid and bismuth, and possesses marked cicatrizing and antiseptic properties, while its non-soluble nature in all ordinary media renders it free from toxicity.

As an antiseptic the gallate of bismuth has not been found equal to iodoform, but its lack of odor is a point in its favor. Applied to the healthy skin, in powder or solution, no effect is produced, it causes no irritation, and when applied to ulcerating surfaces or open wounds it produces no pain. Experiments have shown that it prevents the growth and development of micro-organisms. Clinically, it is found to be a valuable cicatrizing agent, and wounds heal up favorably under its use. So far as having any particularly prominent or pronounced action upon the skin or upon skin diseases is concerned, dermatol is a misnomer. I have used it more as a dressing for wounds and after operations, instead of iodoform, more than I have in skin diseases, as already mentioned; in the few skin affections in which it has been tried it seems inferior to aristol, though an improvement on europhen. A burn of the foot and several burns of the second degree in children, healed nicely under a two per cent. ointment.

In several cases of varicella I covered the individual lesions on the face with dermatol in plaster, with the view of preventing pitting. No pitting took place. I have used it in collodion as a wound dressing and in slight lesions of the skin with good effect, in ointment with lanoline and vaseline, and at the hospital in vaseline alone in ten per cent. strength. It can be mixed with starch or talcum, or both, for dusting-powder purposes in intertrigo, eczema, etc., and for hyperidrosis pedum. In ulcers it is inferior to the other powders so far as stimulation of a flabby or indolent base is concerned. It can be combined with zinc oxide and starch to make a paste.

Pyoktanin I have not found of much value in skin cases. In six cases of inoperable cancer, in which I have tried it both as a local dressing and in interstitial injection, I have found it to give much relief to the patient, and in some instances has very markedly decreased the size of the growth. Internally, from three to five grains of methyl-violet daily have seemed to produce little effect, but incidentally I found it very beneficial in cystitis.

Locally, in gonorrhœa, it seemed to do some good, but internally in one case its action was nil. Thirty-eight cases were treated with injections, gr. ss. to ℥ j.; 12 only remained under observation, 8 were cured, 3 improved, and 1 not improved. The average time of treatment for the 8 cases was four and five-eighths days.

Cases of poisoning from methyl-blue have not been reported, but at the last meeting of the Dermatological Society, Dr. R. W. Taylor, who had ordered three grain capsules for a case of cystitis, reported that the man had taken by mistake two capsules at a dose, and as a result presented himself with a severe dermatitis of the face and hands.

Fuchsine, employed in one per cent. solution in alcohol or collodion, has had some reputation in ulcers, lupus, Paget's disease, epithelioma, eczema marginatum, moist eczema of the hands, and kindred diseases. I have seen a number of cases so treated, but have failed to note any marked beneficial effect. It is the hydrochlorate of rosaniline, and is supposed to combine with micro-organisms.

Creoline, in strength of two per cent. or less in solution or ointment, gives good results in some forms of eczema. It appears to be a powerful antiseptic, but its odor is unfavorable to its use in private.

Thilanin, prepared by the action of sulphur on lanoline, and containing three per cent. of the former, has recently been introduced, and the first has just arrived in this city. It should, from theoretical grounds, prove an excellent remedy for many forms of eruption, since sulphur is one of the most valuable remedies we possess in combating skin diseases. Saalfeld has found that results can be obtained with it which an ordinary three per cent. sulphur ointment will not produce without, at the same time, occasioning an irritation wholly undesirable.

Deodorized Iodoform.—In the *Journal of Cutaneous and Venereal Diseases* for 1886, I gave the result of my attempts to find a way of making iodoform inodorous, and reviewed the suggestions of the various essential oils, tonka bean, or cumarin (which, by the way, has till recently been one of the best in strength of four per cent.), balsam of Peru, coffee (objectionable because fifty per cent. is required), quinine, charcoal, etc., and my conclusion was that none of the methods was satisfactory. Almost any of the ethereal oils will disguise the odor for a time, but so soon as they evaporate, which is not long, the mask is removed. Up to that time I had found non-ethereal oil of sassafras (two drops to the drachm) the most satisfactory. The oil of Canada snake-root (ol. asari canadensis) in the same strength is also efficacious while in bulk, but as soon as rubbed upon the surface the original odor appears. Ethereal oil of coriander, four to eight drops to the drachm, disguises the odor for several days, even when applied to the body. Another suggestion for an ointment is to add one part of creoline to every two parts of iodoform. This surely prevents the smell of iodoform being noticed, but at a sacrifice which will make many nostrils revolt.

Mr. Tsheppe, of the firm of Tsheppe & Schur, has called my attention to heliotropin as an efficient means of rendering iodoform inodorous. This is a synthetical preparation made by Schimmel & Co., of Leipzig, and is rather expensive ($7 per ounce), but only two per cent. is required to give an odor to iodoform which will last as long as the iodoform.

Now, having these means of, at least for a time, wholly disguising iodoform, and probably in one way of doing so permanently, is it so essential to find a substitute, since the odor is the chief objection. Iodoform has not been supplanted by any of the newer would-be-substitutes, and probably will not be wholly, at least for a long time, as it has many useful properties, and surgeons are not going to give it up until quite sure of some better, if not cheaper, substitute.

Stearates have recently been introduced to take the place of oleates. It is probable that the stearate of zinc and of mercury will find a permanent place in the armamentarium of the skin man. The zinc makes an adhesive powder, and in some eczemas appears to have a healing action.

Permanganate of Potassium has proven itself to be an excellent detergent wash in strength of gr. j. to ʒ j. in hyperidrosis pedum. I have used it to some extent in eczemas, ulcers, ivy poison, pustular eruptions of septic origin, etc., and am convinced that it has a value not yet appreciated. It has been used in Russia in burns and frost-bites of first and second degree; I have used it in one or two cases of burn, but without much to be said in its favor.

New Bases are glyco-gelatine, bassorin, and plasment. The first are simply mixtures of glycerine and gelatine in varying proportions, to make a soft or hard mass when combined with zinc oxide and other remedies. They make a protective dressing when painted over diseased areas. Bassorin base was introduced by Mr. Lascar, the apothecary at Demilt Dispensary, and brought to the notice of the profession by Dr. Elliott. Bassorin gum, water, glycerine, and dextrine are so mixed as to make a jelly-like mass with which various medicinal agents can be incorporated. I have found it to fill the indications in a number of cases.

Plasment is a very similar base, made from some form of moss. It was introduced to the New York dermatologists by Dr. Fox, and is made by the firm of Daggett & Ramsdell. I have used it with a variety of drugs, including europhen, dermatol, and aristol. My impression is that unless made freshly or incorporated with an antiseptic, it does not keep well or give satisfaction to the patient. I would advise against dispensing it in metallic tubes when minerals are used, especially iodine preparation, bismuth, and lead.

A comparison of several powders, taken from experience of others as well as my own, will be found in the following table:

	Aristol.	Bismuth Oxyiodide.	Dermatol.	Europhen.	Iodoform.
Odor	.....	.....	.....	Saffron or somewhat like iodoform; faint.	Makes substitute desirable.
Solubility	Soluble in oils, ether, chloroform, etc.	Insoluble	Insoluble	Like aristol	Soluble.
Toxidity	No absorption effects	.....	Not toxic (headache produced). Cases reported.	Not toxic in internal dose of gram. 1.5 daily. Poisonous to animals.	Occasional poisonous effects.
Local irritation	None	None	None (dermatitis reported).	.....	Often causes dermatitis.
Price	35 cents per drachm	10 cents per drachm.	15 cents per drachm	35 cents per drachm	10 cents per drachm.
Internal use	In rheumatism and neuralgia.	Yellow subiodide, gr. v. to xx.	As substitute for subnitrate, gr. xxx.	Subcutaneously in syphilis.	Internal remedy.
Antibacterial qualities	Cultures not retarded. Not marked.	Antiseptic	Slight antiseptic; less than iodoform; no effect on dried cultures.	Arrests development of micro-organisms; does not destroy them.	Antibacterial; no effect on dry cultures.
Analgetic effect	.....	.....	.....	Decided.	
Antituberculous action	.....	.....	.....	Same as iodoform	Well established.
Iodine present	Rich; forty-five per cent.	Rich	None	Twenty-eight per cent.	
Iodine present given up	.....	Freely, though stable.	.....	Less than iodoform; urine shows none.	Gives up iodine when injected.
Stimulant effect	Favors granulation	Marked	Not in torpid ulcers.		
Epithelial producing and cicatrizing effect.	Most marked	Marked	Favors epithelial growth; marked; desiccating.	Marked.	
Physical properties	.....	.....	Not hygroscopic but absorbent.	Must be protected from light and moisture.	Hygroscopic cakes. Waste.
In chancre	Inferior to iodoform	Excellent	Useful	Better than aristol or iodoform.	Good.
In chancroid	Good	Good	Not good	Better than iodoform.	
Balanitis	Good	Good.			
Psoriasis	Good; inferior to chrysarobin	No effect	No effect	No effect, or only slight	No effect.
Parasitic diseases	Tricophytosis, chromophytosis. Good.	Slight	.....	Good	Slight.
Eczema	Too drying as powder in some cases; in moist excellent.	.....	Good dusting powder	Where stimulation is needed.	Little use.
Ulcers	Excellent in indolent and malignant secondary; only affects surface unless dissolved.	Very good, especially in indolent.	Not sufficiently stimulating for indolent; decreases moisture. In phagedena.	Good; equal to aristol in ulcerating lupus, epithelioma, etc.	Good. In phagedena.
Burns	Two per cent. ointment	.....	Two per cent. ointment	Hæmostatic	Good.
Incompatible	With hydroxides, carbonates, metallic oxides, starch, corrosive sublimate.	.....	Mixes with starch	.....	With corrosive sublimate.

696 Madison Avenue.

A CONTRIBUTION TO THE TECHNIQUE OF MASTOID OPERATIONS.

By ALBERT H. BUCK, M.D.,

NEW YORK CITY.

CLINICAL PROFESSOR OF DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA COLLEGE; CONSULTING AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY.

DURING the past year I have, in nearly all my operations upon the mastoid process, made use of a simple contrivance which serves the purpose of indicating, in a trustworthy manner, the relations of the mastoid antrum to the visible field in which our operative procedures upon the bone must take place. This field, owing to the fact that we are not warranted in laying bare an unlimited area of skull surface, presents ordinarily to the observer no characteristics which may readily distinguish it from any other portion of the skull of equal extent. As a means of ascertaining with some degree of accuracy the locality in which the antrum is to be sought for, I have always considered the upper and posterior curved margin of the orifice of the bony external auditory canal as the landmark which I could follow with a sense of almost absolute security. Ordinarily, however, this landmark is not exposed to view. It is usually located by aid of a stiff silver probe, or a steel director, which is made to crowd the soft parts far enough forward to permit it to enter the osseous canal. The instrument is then withdrawn, and we proceed with our work upon the bone, endeavoring all the time to carry the locality of the recently demonstrated landmark in our mind. But this attempt to memorize the exact situation of a given spot soon proves unavailing, and we are obliged to resort to the use of the probe or director a second time. Thus, in the course of the operation, it may be found necessary to relocate the landmark half a dozen times. To obviate this difficulty, and to supply a trustworthy landmark which should be constantly visible during the progress of the operation, I devised the hook which is shown in the accompanying cut (Fig. 1). Originally it was not provided with the small, round, projecting knob, but I found that the oozing of blood in some cases was so constant and so copious as to conceal the greater part of the hook, and I therefore had the steel knob added as a means of showing conspicuously the exact location of the curving upper margin of the external auditory canal.

FIG. 1.—Mastoid Hook-guide. (Reduced one-half in size.)

FIG. 2.—Dissection of the Mastoid Process, showing the Relations of the Pneumatic Cells and Antrum to the External Auditory Canal. The upper ends of the bristles may be seen projecting into the cavity of the antrum. (From Nuhn's Atlas of Surgical Anatomy; slightly reduced in size.)

The curved sharp end of the hook is to be introduced from above into the orifice of the external auditory canal, between the soft parts and the upper margin of the bony orifice. The instrument is then to be kept firmly pressing against the surface of bone by the assistant who is administering the anæsthetic. The long axis of the instrument, when in its proper position, should correspond approximately with the long axis of the body of the patient. A glance at the accompanying anatomical cut (Fig. 2) will convey to the reader a better idea of the relations of the steel knob—the position of which at the orifice of the canal can easily be supplied by the imagination—to the mastoid antrum than can be afforded by any mere verbal description.

Finally, I may add the remark that in order to operate comfortably and with adequate thoroughness, a large external incision is desirable, and preferably one that is curved (horizontal above, curving gradually into vertical below). In very young children an incision of one inch and three-quarters may suffice, but in adults we shall require one of at least two inches and three-quarters, and sometimes, when the tissues are much infiltrated, one of even four inches in length. Another important aid is afforded by an extra broad retractor, either solid, as preferred by Blake, of Boston, or fenestrated, like the one shown in the accompanying cut (Fig. 3). By the aid of such a retractor the flap, composed of the auricle and immediately surrounding soft parts, can be drawn well forward, thus increasing to the fullest extent the area of exposed bone surface.

FIG. 3.—Large Fenestrated Retractor for Mastoid Operations. (Reduced one-half in size.)

CRIMINALS THE PRODUCT OF HEREDITARY DEGENERACY.

By SOPHIA McCLELLAND, M.D.,

NEW YORK.

THE universe is a system of matter by matter for matter. The nervous system is the expression of the spiritual self; the material form of the expression made visible. Every inquiry into the relations between physics and morals—the spiritual—comprises the influence of the moral on the physical, and the influence of the physical on the moral. Every mental state implies a corresponding physical state, and the nervous system is the physical condition of moral phenomena, and a variation in the one is associated with a variation in the other. The brain must be used and nourished like every other organ if its functions are to be fully developed. If this be neglected, or cultivated in a wrong direction—if the organs of the understanding, reason, and judgment are allowed to remain inactive, and the organs of feeling and imagination stimulated and favored, the whole brain is crippled, and one part nourished at the expense of the other.

Now, if we accept this hypothesis—a view now taken by the most advanced scientists as a recognized fact—on the ground of the relation of morals and ethics to the physical, can we not find in the past a starting-point from which nature has fashioned descending generations? Can we explain the cause of the fearful increase of crime of every description, intimately connected not only with the social conditions of the community, but with that of the country at large—the decay of faith—the besotted sensualism—the trampling upon the relations of husband and wife, parent and child, master and servant, ruler and subject—the impatience and restlessness under the just restraints of law—the looseness in government and laxity in discipline—the enormous increase in divorce suits—the swelling of

our criminal lists, so that our penal institutions are overcrowded—the suicides, and the worship of devils? Probably we shall find in the past, not so far back as the Deluge, a starting-point.

The early stimulation of character through the pioneer period has irritated the nervous system of the people of our country into impulses that have caused an abnormal activity and a serious disturbance of the general physiological balance, and that increased nervous nutrition demanded by the new life and its consequences has tended to physical deterioration from the type of the parent race. Furthermore, twenty-five years ago the circumstances of the times were favorable to the development of morbid sentiments—four years of incessant war with its battles and sieges, exciting violent emotions of various kinds, quickened nervous sensibilities, which became exaggerated, like an hypertrophied organ, from excessive development.

The people were a prey to wild passions, tossed from heights to depths, sudden as a thunder clap; they reasoned little but felt much. During this feverish storm of emotions and of impressions, cool, calm judgment appeared at a disadvantage, the bravest and best of the nation were swept away, while we are to-day suffering from the deplorable consequences in the deterioration of its breed.

We should not in matters intellectual or moral, any more than in matters agricultural, expect to reap where we have not sown, or to gather where we have not strewed. One of the most difficult lessons to impress on any mind is the power and extent of individual influence. If it makes no impression on a man to know that God will visit his iniquities upon him, he cannot blind himself to the fact that nature will.

Visit a prison or a mad-house and see Nature squaring her accounts with sin, carrying out her heavy sentences for violated laws. Science begins with the investigation of laws—it is perfected only in the determination of causes. In the light thrown by these laws on the development of the human organism, we discover that bad and unfitting conditions of existence are the cause of perverse and inharmonious development, and that an improvement in these conditions would effect a corresponding improvement in the individual. Revelations of scientific research have proved that there are conditions of the brain in individuals, guilty of sudden and unexpected outrages of the laws of morality, beyond their control, as well as the suicidal or homicidal mania, which can be surely traced to the mental state of the parents, not only as relating to their repugnance to the condition of maternity, but in their efforts to destroy the embryo.

Nerve structure is handed down from parent to offspring, giving each individual a personal capacity which, though capable of being modified by education and influence of environment, is depending on actual organization. It has been clearly demonstrated that nerve energy only exists within the boundaries of nerve structure, and that it varies in expression only when there is a variation in the nerve tissue; this applies to every form of nerve energy, whether it be a simple sensation or the exhibition of thought, reason, and will. I have noted the inheritance of individual peculiarities, and found that they were illustrative examples of the heredity of morbid conditions, imperfections, and anomalies in the intellectual and moral world, as the origin of the monstrosities which we see in the physical are to be attributed to hereditary organic influences. Hence criminals are such, either because they inherit a brain structure incapable of generating moral faculties, or through the influence of repressive environment the development of mind does not evolve sufficient moral strength to guide and control the lower propensities of man's nature. They cannot entirely overcome and negate that which lies in silence, and in strength, behind the organization, and which so imperiously directs action and thought.

Although the intelligence may be acute, and the reasoning faculties may be in a high state of development, yet with all this there is a moral deficiency and perversity of thoughts and desires, with violent passions, which are uncontrolled by the moral faculties, not because the perversities are greater than in other men, but because the moral force is less.

Cause and effect are as unvaried in the intellectual and moral as in the physical world; and through heredity the physical, intellectual, and moral forces of the ancestor largely determine the physical, intellectual, and moral forces of the offspring. Thus we find the number of really healthy, vigorous, and reasonably well-born and well-trained children who ever fall into a career of crime is exceedingly small. Even the accidental fall of such persons always admits of rescue. We have passed hours in the Court of General Sessions in this city (New York), and noted the criminals as they stood before the bar; fully eighty per cent. of these were evidences of arrested development—brains that had been pinched by poverty from father to son for a hundred years, or the offspring of inebriates, epileptics, or those whose pre natal conditions were such as to impress them with an unstable brain.

There are conditions in the nervous system which are neither disease nor crime, yet by adverse circumstances may lead to both, or a development through power of resistance and endurance favorable to recovery.

We see in childhood predispositions to special nervous affections which are not disease, but easily assume conditions favorable to this development through any disturbances of the health of the body from its normal state. Thus, for instance, we see in infancy convulsions, hysteria, nervous irritability, neuralgia, fainting spells, palpitations of the heart and vertigo, melancholia, and eccentricity—these are neither diseases nor crimes, yet by improper development may lead to both. The great factors are heredity and degeneration; but favorable or untoward influences may develop two different results from the same congenital structure, thus the same nature that reveals a perfect angel could become a splendid devil under different developing circumstances. The environment and formation of the earliest habits is the determination of the future man and woman, but perfection of function is the highest result of happy heredity.

There are physical peculiarities which are common to all the degenerated, the insane, the neurotic as well as the criminal. These deficiencies are sometimes in one part of the organism and sometimes in another, but are always associated with deficiencies in the tissues of the internal organs, produced from causes arising during embryonic life. These unfortunate individuals have inherited incapacities of various kinds, morbid cravings, strong passions, and feeble wills to resist temptations; many with defective education from lack of mental power and stability.

There are others whose moral control is so deficient, whose brain is so abnormal from inherited morbid conditions arising from various neurotic affections, that they can only with the greatest difficulty resist temptations from without, or morbid impulses from within. There is an impaired, defective, or diseased condition of the nervous tissue that inevitably results in crime, just as certain other conditions of the nervous tissue results in epilepsy and insanity. This should be defined as a degenerative psychosis of the epileptoid group. The physical peculiarities are easily recognized of the criminal type in a development that would naturally result from the constant use of their faculties in criminal ways. Some criminals possess keen intellects, but their mental qualities are peculiar, and are mainly developed in the line of cunning and scheming, although there are many degrees from the "queer" and "eccentric" individual to the lunatic who is wholly irresponsible.

During the last of the past and the present century there has been a change in the character of crime. A French scientist has observed this curious fact, that the prevailing types of crime have varied with every phase in the progress of civilization. Thus piracy and infanticide have steadily decreased; highway robbery, too, has de-

clined, while theft has considerably increased, as well as certain stealthy forms of murder which have successfully baffled the law. The criminal history of the last two decades seems to prove that criminals begin to master the difficulties of circumstances in a way which threatens to make discovery next to impossible. Poison, for instance, has made great progress in science, so that those who are skilled are able to cover all traces of their crime by taking the precaution to use more than one drug. Only a few months ago one of the experts consulted in the trial of Harris, the medical student accused of causing the death of his wife, quoted the opinion of several eminent specialists to this effect: "No chemical analysis can pretend to trace the vestiges of certain poisons as modified by the subsequent administration of other drugs."

Drs. Ferens and Delat have demonstrated that insanity is much more frequent among criminals than in other persons; that crime and insanity are closely connected; that a large percentage of criminals, before they reach the age of twenty five, give evidence of hereditary neurosis. The innate weakness and instability of their brain is shown by the number of criminals who become insane in jails, which is ten times higher than it is in the free population outside. In asylums we find many lunatics who resemble criminals, and in jails we find many criminals who resemble lunatics.

Huxley says that "theft and murder are the result of activity of special theft and murder cells in the gray pulp," while Benedict, one of the most famous physiologists and pathologists, in his work on "The Brains of Criminals," has arrived at the following conclusions: "The brains of criminals exhibit a deviation from the normal type, and criminals are to be viewed as an anthropological variety of their species, at least among cultured races. The constitutional criminal is a burdened individual, and has the same relation to crime as his next-of-blood kin, the epileptic, and his cousin the idiot, have to their encephalopathic conditions. The essential ground of abnormal action of the brain is abnormal brain structure." The appreciation of these facts is likely to create a veritable revelation in ethics, psychology, and jurisprudence.

The transmission of all kinds of psychological anomalies—whether of passions or crimes, or of hallucinations and insanity—is so frequent, and evidenced by such striking facts, that morbid psychological heredity is admitted by those who have no suspicion of a law which is far more general.

If we restrict ourselves to two sorts of cases, where disorders of the intellect correspond to changes in the tissues of nerve-centres, and those in which the brain presents no apparent degeneration, but the individual has voluntarily become hardened and dangerous—the criminal by profession—characterized by expressed physical signs resulting through heredity from innate physical conditions fashioned by imitation for generations.

The similarity of the features of this class of offenders may be explained by the similarity of their habits. Heredity is a biological law, which itself results from another law, that of the transfer, by generation, of the attributes of physical and mental life; and the laws of generation govern everything that lives—the plant as well as the animal. And there is not one part of the domain of life subject to the laws of heredity and another part exempt from them. This work is but an essay, and will only serve as a basis and plan for our exposition, for we are compelled to grope our way. This study would require a volume. For our purpose it will suffice here to show by some facts what the unconscious activity is, and in what degree it can explain the correlation of the physical and the moral.

First, it might be held that psychological heredity is the cause of physiological heredity. This proposition is evidently the one that is maintained by the idealists. It is worthy of remark that while spiritualistic philosophy has been much occupied with the future destiny of the soul, it has bestowed very little thought on its origin. It has inquired whither we are going, and but seldom whence we came. And yet these two problems are both equally mysterious.

The soul inherits from its parents certain determinate forms of sensitive, intellectual, and voluntary activity, and it contains these virtually. The soul thus constituted now sets about fashioning its body. Follow its labors from that moment which caused Harvey so much astonishment, when he "saw slender threads like those of a spider's web, stretch out from one corner to another of the matrix, and then saw this net-work forming a sac which held a white liquor in which appeared the punctum saliens. Follow this evolution, whose aspect changes sometimes from hour to hour, and whose instability affects the most essential no less than the most accessory portions, so that it might be said that the unseen workman is feeling his way, and that he completes his work only after many a mistake. Pursue your observations to the moment when embryonic life is at an end, and extra-uterine life begins, and then see how evolution still goes on until the being is fully constituted; and you must confess, perhaps unwillingly, that all this is wonderful work, which, in spite of errors, anomalies, and deviations, is not the effect of chance, and that it is not without intelligence, though without consciousness. Here the soul is the cause, the organism the effect, consequently, the conclusion is quite natural that the nature of the soul implies that of the body, and that the ground of physiological heredity is to be sought in psychological heredity."

Lombroso, the leader of the Italian school, thinks that every criminal is the product of a degenerate individual whose physical characteristics bear mark of the primitive savage, born in a wild condition, and fatally condemned by their organization—both materially and morally—to theft or murder. Are these remnants of an ancient, coarser, and more cruel age? or are they simply madmen? The skulls of a number of murderers and highwaymen present evident exaggerated characteristics of the savage, and would bear out this supposition. Either idea has been upheld by Lombroso, who, after having considered the criminal as a savage, has now come to consider him as a madman, in the moral sense of the word, without entirely abandoning his first opinion.

In England and in France there is a tendency to identify the criminal as morally insane, in other words, the criminal is a madman, though he seems to have a purpose in his crime. There are others again who class the criminal by birth among the professional types, as we have said before, just as men are born soldiers, artists, and poets. Whatever may be the action on the organism of a murderer of the kind of life which he leads, there is a great resemblance between all criminals, which bears no similarity to the habitual expression of young prisoners, which has been modified by the differences of their surroundings from those in which they had lived previously.

Civilization is a very complex condition, a moral atmosphere to which man has to become acclimated. There must be a correspondence between the moral man and his moral conditions, as between the physical man and his physical conditions. Whoever cannot adapt himself to new conditions of social life must die out—gradually, perhaps, yet surely.

There is always in every community a proportion of brains, which, being brought into action, will break down. This proportion doubtless diminishes as the community is elevated, and in a very few generations the result of culture may—perhaps will—be to develop a better stock, looking at the people as a whole; but at the outset of the educationary process, and in the generation first taught, the immediate result must be a considerable number of wreckings.

This general principle is applicable to all races, peoples, and classes, and it explains why the first effect of

trying to elevate the negroes has been to produce an apparent increase of insanity among them.

Functional nervous diseases and irritable nervous action, as well as abnormal conditions of the physical life, are found in a large percentage of cases in the descendants of those whose predecessors were addicted to drinking alcohol and its ingredients. Confirmed drunkenness of the parent was as potent as actual mental deficiency to predispose his children to the development of insanity. Alcohol first excited, then paralyzed in succession, every nervous centre in the body.

Epilepsy, insanity, chorea, hysteria, and asthma, in some families are found interchangeable with this habit. Statistics show these diseases to be largely incidental to the period of growth and development. Among two hundred and twenty-five cases, in over fifty-five per cent. these diseases made their first appearence before the age of twenty-five, and in over thirty per cent. they appeared before the age of ten.

Demme, by careful research and examination into the history of ten families of drinkers and ten families of temperate persons, elicited the following facts: The direct posterity of the ten families of drinkers included fifty-seven children. Of these twenty-five died in the first weeks and months of their life; six were idiots; in five children a striking backwardness of their longitudinal growth was observed; five were affected with epilepsy; five with inborn diseases. One boy was taken with chorea and became idiotic. Thus of the fifty-seven children of drinkers only ten, or 19.5 per cent., showed a normal constitution and development. The ten temperate families had sixty-one children, five only dying in the first weeks; four were affected with curable diseases of the nervous system, two only presented inborn defects. The remaining fifty—81.9 per cent.—were normal in their constitution and development.

From this series of investigations we derive the sad truth that among the children of drinkers the prevailing mortality is fearful; that the survivors represent a pitiful crowd, afflicted with unsoundness of mind, idiocy, epilepsy, and other disturbances of their nervous system, and then only a very small proportion of the descendants grow up as useful members of society.

Rev. Peter Thompson, of the "London Mission," in an essay read by him at the recent Ecumenical Council at Washington, stated of the population of London over one million three hundred thousand are in poverty, more or less acute. In St. George's in the East, forty per cent. of the population belong to that class. Every thirty ninth house is a drink-shop, and forty-five per cent. of the adult deaths occur in the workhouse. Such conditions are absolutely appalling. The census statistics show that there are seventy-three thousand paupers in this country. Among the impure and fallen there is need for adequate provision of home life and employment.

There are many individuals who are suffering from inebriate inheritance transmitted from their predecessors, so that the smallest portion of alcohol or its ingredients plunges them into a state of intoxication, with the risk of committing some criminal offence, not intentional while under this influence. Whoever is held responsible for his aberrations and his wrong-doings is termed, and is punished as, a criminal. Whoever is considered irresponsible is no longer a criminal to be punished, but a lunatic against whose vagaries society takes pains to protect itself. The accused may not be wholly unconscious of the nature of the act, but he is beyond his own control, and powerless in this partial state of consciousness to resist his impulses. "Crime is the result of an evil impulse which ought to have been controlled, the controlling powers are the cerebral functions of judgment and will."

In England, France, and America, drunkenness is considered an aggravation of the crime, and should demand additional punishment. We remember, thirty years ago, a case where a young man, about sixteen years of age, was brought before the bar for theft, without any apparent motive, during an unexpected drunken outbreak. While standing in court he was suddenly seized with an epileptic fit, his first attack, and carried unconscious out of the court room. Because of respectability and good social standing of the family this case excited the greatest interest in the community where it transpired. Expert medical testimony was summoned on both sides at the subsequent trial, to prove or disprove the responsibility of the accused. A man of rare scientific attainments—Wible, of Kentucky—decided that the evidence clearly proved marked neurosis, and quoted Marshall Hall in support of his decision. Therefore he adjudged the accused as morally irresponsible of felonious intent. The prosecution summoned a number of witnesses who entertained an adverse judgment, which the Judge sustained, and the accused was not only held guilty of the act, but additional punishment was meeted out for the intoxication as an aggravation of the crime.

We have been able to trace the health history, with fairly complete account, for four generations of this case, marked Case I., as appended below. The question of the tendency of a family to morbid, mental, or physical conditions during two or more generations, of more or less varying kinds, is difficult to work out perfectly, though in a large number of instances we may get enough information to be very useful.

I have spent much time and trouble in endeavoring to collect such information; but there are two main difficulties in connection with all such attempts. From hospital patients and the criminal classes you frequently can get no reliable information whatever respecting any members of the family farther back than the immediate parents, and even respecting uncles and aunts and first cousins it is often impossible to learn anything. And when you get to a higher class of society, although the information may exist, it may be withheld, or you may be purposely mystified.

I shall now give the results of special inquiry in Case I., which by the kindness of friends I have been able to carry out.

Case I.—The great-grandfather of the young man mentioned above was a man of splendid physique, who lived very freely but died an old man—had suffered occasionally from sciatic pains and gout. His children, three sons, though strictly temperate, were men of eccentric and somewhat violent temper. One married a lady who died of phthisis, and among the ten children she bore him two sons died of phthisis, two sons became chronically insane, one son died of tubercular disease (aged fifty-six), two sons were living, at last account, at advanced ages, and have always been perfectly healthy and strong. One daughter died in middle age, not certain from what cause; one daughter lived to the age of eighty-six and then was attacked by erysipelas, followed by violent epileptiform convulsions—this continued for the remaining three months of her life.

The fourth generation of this branch of the family consisted of thirty-one individuals, of whom seven have died of scrofulous diseases, one from violence, and one from rheumatic fever. Among the survivors twenty-three have been insane, one recovered, one had a severe attack of erysipelas, corneitis, and iritis; one has been a sufferer from chorea, one has become phthisical. The remaining sixteen enjoy good health, but are distinguished, almost without exception, by a marked nervous temperament, indicated by an anxious tendency of mind, quickness of perception, æsthetic tastes, disposition of alternations of impulse and procrastination.

Case II.—A gentleman; highly nervous temperament; sciatica. Father died insane from drink, and other members of the family also, nearly or quite insane.

Case III.—A gentleman, aged fifty four; cerebral neuralgia; a great whiskey-drinker. Drinking hereditary for three generations. Father died insane, grandfather epileptic, sister phthisical, two brothers very eccentric.

Case IV.—Intercostal neuralgia in a girl, aged twenty-

four. Mother and two uncles phthisical, maternal grandfather epileptic and a drinker.

I shall conclude this part of the argument by stating the general result of my inquiries respecting sixty four hospital patients confined in prison (Jeffersonville, Ind.), 1878–79. I obtained evidence of the following diseases existing among themselves and their blood-relations: Epilepsy, fourteen cases; insanity, twelve cases; and drunken habits, fourteen cases. "Consumption," eighteen cases; "St. Vitus's dance," six cases. I am well aware these figures must be taken with caution, and that considerable doubt must rest on the accuracy of some of these details, more especially with regard to epilepsy, as it was impossible, with the greatest care, to be sure that this was not given by mistake for hysteria in some cases; and the same may apply to the statement that relations had suffered from "consumption."

The facts are given for what they are worth, and with the express reservation that their total reliability is far less than that of the account obtained from private friends who would usually be more prone to reticence on such a topic. This question is a mixed one of science and law, and is undergoing an examination at the present moment by the two professions in England. Sir Henry James, in reply to a letter of inquiry addressed to him by Sir Lyon Playfair, writes the view entertained by English law. This is, that in minor offences drunkenness is to be regarded as an aggravation—that when a man knows that drink makes him violent he is deserving of double punishment, first for the offence, and next for voluntarily incurring the state that invites its commission. If a man drank in order to inflame himself to the commission of a meditated crime, he is to be made responsible, whatever his mental state at the moment of the act.

But when it comes to the higher grades of crime and pathologic mental conditions originating in alcoholism, Sir Henry confesses to a difficulty, and his efforts to formulate rules are not satisfying, the question assuming an aspect more and more medical.

The doctors propose the word "drunkenness" for the drink habit that carries indulgence to the point of excess whenever it has the chance, and "inebriety" to describe the occasional or periodic outbreak which, however violent, punctuates periods of temperance.

A distinction is likely to be made, on which the English medical and legal experts will agree, between the acts of a maniac and the crimes of a crank. The "inebriate," as described by the medical man, is to have the benefit of the doctrine of irresponsibility which rightly shields the madman; the drunkard is not.

An appeal for total abstinence from intoxicating liquors as a beverage, which has just emanated from the Zurich Society for Combating the Alcohol Habit, presents the subject from a scientific and humanitarian point of view, and the dangers, political and social, which menace the future of Europe by the almost universal use of intoxicants.

Nearly the entire press on the Continent has stirred the communities to their very depths, as well as the recent utterances of the Emperor of Germany, who foreshadows the perils of increasing drunkenness. This appeal is remarkable in two respects. First, in its array of signatures, representing almost all professions, especially the educational and scientific circles. Second, it is remarkable for the strength, tact, and literary character of the appeal itself.

Count Leo Tolstoï is one of the signers of this document, and has helped to fan the flames of agitation throughout Europe. This subject is fast becoming the question of modern civilization. Science has shown beyond question the changes that are wrought in the organs of the body by the often repeated and free use of such beverages. These changes are occasioned by a process of poisoning, in many respects similar to arsenical poisoning, and are recognized as causes of degeneration, sickness, and death.

The direct action of alcohol as a narcotic resembles ether, chloroform, and morphine, and like them brings a more or less profound paralysis of the mental functions. The close relation of these poisoning effects to the social consequences that attend drunkenness and the drink habit begins to make itself manifest to the general intelligence. If it be true that not only the drinker transmits to the child an inferior constitution and a nervous system predisposed to all kinds of maladies, but also that the injurious effects of alcohol increase from generation to generation, it is time that some attention were paid to the peril that is in store for those who come after us. If into the life of every individual be introduced a factor that tends to enfeeble the strong and to kill the weak, must not the effect upon the people as a whole be to diminish the aggregate capability?

The foundation of all those terrible evils of social life, source and centre, arise from pre natal influences and the environments that surround them. These conditions have more influence than all that come after. The only hope for permanent progress lies in the proper education of the children, not alone from their birth and childhood, but before their development—at the vital starting point.

Educate our most intelligent people that man is responsible for the crime and miseries of the race through his own lack of wisdom and knowledge, and that these conditions can be changed through obedience to law. It is of more consequence to our present civilization to consider whether our posterity shall be idiots or insane criminals than if we have descended from apes.

The only means of advancing the race to the altitude which the best specimens foreshadow as the possibility of all, must come through the young men and women of today, the possible fathers and mothers of the future, through equal opportunity and co-operation as builders of the higher humanity.

In the study of nations, the institution of government, and the administration of affairs, man is not a success. His reliance, first and last, is upon force; justice and harmony, fraternity and purity, cannot be brought into human society by fighting. Neither is suppression reform, nor coercion progress, any more than the legislature or the policeman can make men honest or morally upright.

Though man does not bear testimony as a builder of the higher humanity of social progress in morals, his triumphs in material structures, marvellous inventive genius, and patient scientific research, manifest that it is through him to form the forces and elements of man's material needs. Yet, by the most skilful use of the scalpel and the microscope, science has not been able to discover why the moral qualities of humanity should bear such scant relation to the intellectual, so that crime does not diminish as men grow wiser, nor is even human happiness greatly served by all the discoveries of science.

The moral elevation aimed at must be achieved through the co-operation of woman, through the spiritual realm of the higher nature. In the order of all things she is a link between the material and spiritual, especially in her creative function, to give bias to the physiological and psychological processes of embryotic growth.

The administration of law will be in a healthier state when science and judicial theory combine in administration. Man will never be able absolutely to prevent the increase of crime until the development of noxious organisms are checked. The state should see that those who are criminals through heredity be imprisoned in an asylum arranged for the purpose, fed on wholesome diet, and made to work as much as their condition will allow. The detention to which they are doomed will favor the extinction of their class, as it will prevent the propagating their kind. Furthermore, those criminals who have been guilty of rape should be rendered physically incapable of future entailment. Annihilation of the criminal has little effect on the development of fresh crimes. We cannot prevent society protecting itself in its own way, but we should demand all the more urgently the radical reformation of society.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 23, 1892.

REFORMATORY TREATMENT OF CRIMINALS.

FOR such as believe in the physical theory of criminal propensity, there will be found much for suggestive thought in the perusal of the recent yearly report of the State Reformatory at Elmira. For sixteen years this institution has endeavored to perfect a plan of reform for juvenile prisoners, based upon the knowledge of the moral and physical defects which presumably resulted in their criminality. Although working in an entirely new field, the results have been very satisfactory, and are likely to prove even more so as the system becomes elaborated and perfected. The principle upon which its course of training is founded is so eminently rational and so demonstrably practical, that it must in the end initiate a widespread reform in prison management. In one sense the Reformatory may be considered as an infirmary for the cure of crime, and the treatment of its varied causes. In other words, the criminal is viewed not as an animal to be punished, but as a human being who, with proper care, can be improved and made a useful member to society.

To quote the language of the report, "Every inmate of the Reformatory is at once a member of the compulsory community, and a candidate for a voluntary community. His detention is a period of preparation and probation for freedom." The sentence as to duration being determined by the degree of progress made, the highest incentive is thus offered for voluntary and cheerful submission to the discipline of development. Fitting each case to its special needs, hereditary proclivities are overcome, bad habits cured, higher moral tendencies encouraged, and physical defects remedied. To such ends suitable trades are selected, certain studies are obligatory, while different gymnastic trainings and military drill round out the necessities for the purely physical requirements of the inmates.

The report further says: "The average period of detention of the 1,290 present inmates is 15 months, and the average detention of those paroled during the past year was 21 months. One hundred and twenty-one men, physically or mentally defective, or abnormally lacking in moral sense, were treated in the gymnasium to systematic physical culture of baths and exercises with satisfactory results. By aid of this treatment some men are improved who would otherwise remain incorrigible. During the year 1,537 different inmates received the benefit of more or less practice in one or more of forty mechanical trades or occupations; and of the 369 prisoners paroled 307 went directly or indirectly to the trades they learned here. Of the others, 26 were paroled to clerical and laboring situations, five to trades previously learned, and 31 entered the service of the Reformatory as guards or monitors.

"The progress of the 1,080 pupils enrolled in the School of Letters at the commencement of the year—October 1, 1890—is shown by their distribution among the classes on their admission and at the close of the year as follows:

	At admission.	At the present date.
Primary Classes	791	384
Intermediate Classes	164	346
Academic Classes	125	350
	1,080	1,080

"Effective military training has been applied this year to 1,637 of the 1,746 inmates. It is mainly by means of the military organization and training that it is found practicable to employ in situations here, for their own benefit and further test of fitness for release, so many of the inmates from the ranks. Forty-six of these are now engaged as subordinate officers, monitors, and employees."

This is certainly an excellent showing, but that yet more is to be known, and much more accomplished, is suggestively set forth in the following extract from the report of the General Superintendent:

"Scientists must yet find for us the true source of antisocial behavior, very likely to be discovered in the material substance, the defective tissue of the man. Then experience must demonstrate the methods and the possibility of permanently changing the channels of nervous action, producing habitually improved conduct, which is reformation indeed. For such an end, it is probable that much more attention will be bestowed upon the organism of the man, and that its preparation for right impressions will be sought from two avenues of approach, instead of one—through the body itself, and by way of the mind. Is it not possible that the activity of interest and scientific research in criminal anthropology, especially in Europe, and the investigations as to the power of suggestion in hypnotism, may supply additional light upon this most obscure of human problems?"

THE SHIP'S SURGEON AGAIN.

WE have so often had occasion to speak in terms of rather less than respect of the ship's surgeon, that our readers may be led to believe that our opinion of his ability is not exalted. And our readers would not be far from the truth. It seems, perhaps, a rather small matter, and one that concerns chiefly those whom business or pleasure sends to sea. And so it would be a comparatively small matter if it concerned only steamship passengers, although even then it would be of considerable importance to those passengers whether their lives were in the hands of a competent physician or an ignoramus. But it concerns a much larger number of people than

chose who cross the Atlantic from or to America, for it is a matter of vital import to every inhabitant of this and neighboring cities, if not of the whole country.

This city is menaced continually by immigrants bringing with them the seeds of disease, and the danger of an imported epidemic is ever present, and can be averted only by the greatest vigilance of the quarantine and city health authorities. It is the duty of quarantine to guard the entrances and keep those ill from contagious diseases from coming to the city; but few can realize the difficulty of such a task. If it is at times a hard matter to diagnose a case of incipient typhus fever or small-pox, even when there is opportunity for deliberation and careful examination, how almost impossible it must be in certain cases to detect a case of contagious disease among four or five hundred or a thousand immigrants moving in line before the quarantine officer on the deck of a steamship! The ship's surgeon, who has had the passengers as it were in quarantine for ten days or two weeks, is the one upon whom the responsibility of detecting contagious diseases should chiefly rest. But in order that the quarantine authorities may place any reliance upon him, he must be known to be competent.

A short time ago a case of typhus fever was detected by the health officer of the port in the person of a Russian Jewess, on the steamship Nevada. The astute surgeon on the vessel had supposed the case to be measles, the possibility of typhus occurring in an emigrant coming from Russian Poland by way of Hamburg and Liverpool seeming never to have entered his head. A man who could make such mistakes as that should not be allowed to practise on any vessel bringing immigrants to this port, and there ought to be some way whereby the United States Government could compel the steamship companies to employ experienced and competent surgeons.

THE GOLD-CURE ABROAD.

The Lancet publishes and discusses seriously and sadly the following item of information:

"The gold treatment for alcoholism and the morphine habit, which has been so largely advertised in America, is now about to be introduced into this country. To-day (Friday) a meeting is to be held at the Westminster Town Hall, under the auspices of the Church of England Temperance Society, and the chairmanship of the Right Rev. Bishop Barry, at which information will be given respecting this treatment and its results in sixty thousand cases. We hope that this information will go further than a mere reference to so many alleged cures. The drug used by Dr. Keeley is stated to be a double chloride of gold, but beyond this nothing is known. The formula, method of use, and dosage are kept quite secret. For twelve years Dr. Keeley is reported as having pursued this treatment at Dwight, Ill., and in that time sixty thousand persons are said to have been treated at the parent home, and at the branches established in various American States, with only five per cent. of relapses."

"Truly," our contemporary adds, "the methods adopted by some American physicians astound us. The running of a secret cure for one's personal profit would, in this country, insure the erasure of the inventor's name from the roll of any college of physicians or surgeons, university or medical society, with which he might be connected."

If *The Lancet* would take the trouble to glance over current American medical literature, it would learn that Dr. Keeley, if he is a doctor, does not hold any position on the roll of any reputable medical society or institution of learning. It would learn also that the gold-cure, so called, is generally regarded by the profession in this country as a purely commercial enterprise, and a form of arrant charlatanry. The claims for the cure are absurd and unsubstantiated, while, whatever be its merits, its secrecy and the purely business methods by which it is worked, have condemned it long ago. It will run its course like the Perkins tractors and the mind-cure.

THE SOUTH AND CHEAP MEDICAL EDUCATION.

The Association of American Medical Colleges has had a somewhat checkered and eventful history. It was organized originally in Philadelphia during the Centennial year. It led a rather precarious existence for many years. In 1884 there were about a dozen colleges on its membership list.

In 1890 it had a new birth, and with the increased interest now taken in advanced medical education, the prospects of its usefulness are very great. At the third annual meeting (new series), held in Chicago this summer, the attendance was good, and over two-thirds of the medical colleges of the country were represented.

The South alone failed to put in its proper representation, and one of the Southern schools formally withdrew from membership. The cause given was of a purely business character. The standard of the Association, it was said, is too high for the Southern medical colleges. Unless they all agree to elevate this standard, the one that steps in advance is "frozen out."

We trust that our brethren in the South will appreciate the situation: Their colleges are confessedly poor, and there can be no advance because the cheaper ones outbid the others. Southern physicians are sensitive to the imputation of commercialism, and they are justly proud of their capacity and resources as educators. We trust that they will speedily take means to correct the opinion which must now be frankly expressed, that Southern medical colleges are cheap colleges, not necessarily because they are inferior in equipment, but because they are low in their requirements.

The Profession in Germany.—From statistics furnished by our German Correspondent, it appears that the number of medical men in Germany registered for the year 1891 was 20,223, against 18,840 in 1890, making an increase of 1,383 for the year. This number is distributed thus: Prussia, 11,129, against 10,784 in 1890, increase 345. In Berlin alone there are 1,615 this year against 1,412 in 1890, increase 203. In Bavaria 2,219 practise medicine, and 2,346 surgery. Saxony has 2,616; Würtemberg, 690 doctors and 305 surgeons; Baden, 608 practitioners; Hesse, 467; Mecklenburg-Schwerin, 225; Hamburg, 376; Alsace and Lorraine, 577. The increase thus appears to be generally diffused.—*Medical Press.*

News of the Week.

Typhus Fever. — Several cases of typhus fever have been discovered recently on vessels arriving at this port, and some additional cases have developed among recently landed immigrants.

Four at a Birth.—A Philadelphia woman recently went to visit a friend, and there gave birth to four girls. The press despatch which conveyed the information also states that the father, who was breakfasting at the time, became greatly excited when the news was broken to him.

M. Pasteur, who has been suffering from cholera in Paris, was reported by the *Gaulois*, some days since, to be dying. We are rejoiced to learn, however, that his illness was not as serious as at first believed, and that he is now fairly convalescent.

Dr. Charles C. Johnson, one of the leading colored physicians of this city, died during the past week. He was born in Lynchburg, Va., on August 4, 1859, and began the practice of medicine in this city in 1889.

Dr. Fraser C. Fuller died at his residence in this city on July 18th. He was born in Boston in 1860, and studied medicine at the Homœopathic Medical College, and later at the College of Physicians and Surgeons in New York, whence he was graduated in 1882. He was visiting surgeon to the Charity Hospital and a member of several medical societies in this city. His death resulted from an injury received in the State camp at Peekskill. He was riding his horse to water barebacked, and was thrown and trampled upon, his right leg being fractured.

Measles in Japan.—There is an epidemic of measles in Tokio and other cities in Japan. The Emperor has been one of the sufferers.

Yellow Fever.—Four of the officers of the steamship Enchantress, which arrived here a few days ago from Santos, died of yellow fever during the voyage. These were the captain, purser, steward, and third engineer. Although it is now winter in Santos, the disease is said to be still very prevalent in an unusually fatal form. A despatch from the City of Mexico, dated July 19th, says that yellow fever has prevailed for some time in Vera Cruz, and still continues unabated. All who can are leaving the city to escape the plague. Many deaths have occurred among the foreign colony.

The Cholera continues to advance in Southeastern Europe. In Russia the disease appears to be ascending the Volga and now has passed Saratov, several cases being reported from Kazan. It is said also that cholera has appeared in Moscow. A number of deaths occurred on a steamer plying the Volga between Astrakhan and Kazan, and in three days there were seventeen deaths of passengers on the Trans-caucasus railway. Russia has extended her influence and commerce in Central Asia through this railroad, but is now paying the penalty, as it is by means of this same highway that the cholera has been brought into Eastern Europe. A serious riot took place in Astrakhan, a number of peasants having attacked the hospital under the impression that the physicians were burying their patients alive. The Minister of War has, in consequence, sent word to the commandants of garrisons to repress any similar outbreaks without delay, using ball cartridges if necessary. A death has occurred in Trieste from what is believed to have been cholera, and several suspicious cases are reported from a village in Roumania near the Servian border. A commission of experts sent by the Spanish Government to Paris to report on the "cholerine," has declared that the disease is true Asiatic cholera. In consequence of this report Spain has instituted a system of inspection along the frontier, and arrangements are being made for the thorough disinfection of the baggage of passengers entering the country from France.

Dr. C. C. Terry, of Fall River, died in that city on July 18th, from a wound received in fencing. The button on his adversary's foil broke and the weapon pierced his eye and entered the brain. He almost immediately lost consciousness, and died in about three hours. Dr. Terry was a graduate of the Harvard Medical School, and was fifty-five years of age.

Bird Tuberculosis as a Prevention of Phthisis.—MM. Hericourt and Richet have been investigating the prophylactic power of avian tuberculosis on dogs. On April 14, 1892, four "unvaccinated" and four "vaccinated" (with avian tubercle) dogs were subjected to inoculations with equal quantities of human tubercle. The culture, forty-five days old, was injected into the saphenous vein, one cubic centimetre being the dose employed. The inoculation was repeated on two subsequent occasions. On the same day three other dogs, already "vaccinated," received a single dose of human tubercle, either in the peritoneal cavity or in the saphenous vein. The results are most striking, for the four "unvaccinated" animals succumbed on the eighteenth, twenty-first, thirtieth, and forty-fifth days, respectively, while all their "vaccinated" comrades are still living, and apparently enjoying perfect health.

The Alumni of the Medical College of South Carolina (Charleston) have organized an association, and will establish and equip a laboratory of biology and pathology. Dr. Eugene Wasden, of the Marine Hospital Service, is President, and Dr. C. B. Calson, of Charleston, is Secretary and Treasurer.

Hereditary Transmission of Mutilations.—Dr. C. G. Lockwood, of New York, has recently published some interesting results of his experiments on the hereditary transmission of mutilations. White mice were selected on account of their rapid breeding, as they begin to breed when they are thirty days old and breed every thirty days. He bred them in-and-in for ninety-six generations, destroying all the sickly and defective ones, and in this way obtained a larger and finer animal than the original pair. His experiments in breeding their tails off were done by selecting a pair and putting them in a cage by themselves and clipping the tails of all of the young. When these were old enough to breed he selected a pair, and when they had young, clipped their tails. By continuing this breeding, in the seventh generation he got some young without tails, and finally got a perfect breed of tailless mice. By taking one with a tail and one without a tail, and alternating the sexes in each generation, he finally again got a breed of all-tail mice.

A Case of Toxic Central Amblyopia Terminating in Progressive Atrophy.—In the article with this title, published in the issue of July 16th, it is stated on page 70 that the acuity of vision in the left eye was $\frac{1}{60}$. Dr. Hinde writes that this should have read $\frac{1}{60}$.

Lesbian Love and Murder.—A young girl, living in Tennessee, formed Lesbian relations with another girl. The latter slackened in her devotions to perverted sexuality, and accepted attentions from a young man. The young woman of the first part thereupon became jealous, and in a fit of passion killed her girl lover, declaring that she could not live without her love. The trial for murder begins, and the claim of insanity is put in defence. The victims of sexual perversion may be in a sense insane, but we very much doubt if the law will hold them irresponsible.

Orificial Surgery.—Besides a railway surgery, an orthopedic surgery, an abdominal, a cerebral, and a pulmonary surgery, there is an oral, and a final and *fin de siècle* development known as "orificial surgery." It devotes itself, we take it, to treating scientifically the various openings of the body. Whether it includes such artificial openings as those made by boils and gunshot wounds, we do not know. But it flourishes enough to support a journal of its own, which comes at $2—rather a high price just for orifices.

Salt and Summer Diarrhœa.—Some years ago we recollect reading a monograph by a learned gentleman, wherein he showed that in cholera there was an enormous loss of chlorides and that by administering these in abundance the disease could be controlled. Experience has not proved this to be true, yet we doubt not that salt is a good thing to make prominent in the summer diet. A layman writes to the *Times* this testimony regarding it: "During the heated term people perspire much, and every drop of perspiration takes salt out of the system. In the hot seasons those scourges are most virulent. I have acted on this theory ever since I read the statement, in summer complaints and cholera morbus, with decided and immediate success in every case. I take a tumblerful of water, add a teaspoonful of raw corn-starch and a teaspoonful or two of common table salt, stir well, and drink it as much and as often as I can without causing nausea. The taste of salt is not ugly when the system needs salt. I have tried this more than a hundred times in cases of summer diarrhœa and cholera morbus, with invariable, prompt success."

The Red Cross Insignia.—The Committee on Foreign Affairs have reported to Congress the bill to protect the insignia and name of the Red Cross. The bill incorporates the American National Association of the Red Cross, and describes the badge as a Greek red cross on a white ground. It is provided that it shall be unlawful for any person within the jurisdiction of the United States to use the symbol of the Red Cross as a trademark or otherwise, and imposes penalties for violation of the law.

The Militia Surgeons of Canada.—The *Montreal Medical Journal* announces that an Association of the Medical Officers of the Militia of Canada has been formed. Over twenty charter members attended the first annual meeting, and quite a number of appropriate papers were ready and presented. Among the officers chosen for the ensuing year were: Honorary President, Surgeon-General Bergin; President, Surgeon, F. W. Strange; Vice-presidents, Dr. Moore, Dr. Roddick, Dr. Connell, Dr. McGillivray, Dr. Jenkins, Dr. Orton, and Dr. Duncan; Secretary, Surgeon G. Sterling Ryerson, of Toronto.

The Twentieth Annual Meeting of the American Public Health Association will be held at the City of Mexico, Mexico, November 29, 30, and December 1, and 2, 1892. The Mexican Government has interested itself in the work, thereby assuring the success of the meeting. All the details are in the hands of federal officers of the Republic of Mexico. The general Government has requested every State to send delegates. Invitations have also been extended to Central and South America. The session will continue four days, and owing to the expected large number of papers the Association will probably, for the first time, do its work in sections. Prominent sanitarians and scientists from the United States, Canada, Mexico, and the Central and South American republics will take an active part in the meeting.

Proprietary Medicines.—The Missouri State Medical Association has adopted resolutions condemning the practice, on the part of physicians, of giving certificates to manufacturers and proprietors of medicines, and also recommending to the profession the future discontinuance of such medicines.

Dr. George W. Van Voast, one of the oldest and most prominent physicians of Schenectady, died there suddenly on July 14th, of heart failure. Dr. Van Voast was a graduate of Union College, and also of the College of Physicians and Surgeons of New York. He entered the army and served until the close of the late war.

Yale Medical Department.—The seventy eighth anniversary of the Medical Department of Yale University was held on June 28th. The address in medicine was delivered by George M. Sternberg, M.D., of the United States Army. Twenty-two graduates received the degree of M.D.

Obituary.

CHARLES D. SCUDDER, M.D.,

NEW YORK.

Dr. Charles D. Scudder, a well-known physician of this city, committed suicide at Northport, L. I., on July 19th, while temporarily insane. Dr. Scudder had been suffering severely from nervous prostration for some time, but no such tragic ending of his life was in the least anticipated.

Dr. Scudder was born in this city in 1855. He was graduated from Trinity College, Hartford, in 1875, and from the College of Physicians and Surgeons, New York, in 1878. After graduation he studied abroad for a time, but returned to New York and began to practise about eight years ago. He had an extensive practice and was most favorably known among the profession. He had made a number of valuable contributions to gynecology. He leaves a widow and one daughter. He had many warm personal friends among the profession in this city, who have been both shocked and grieved to learn of his sudden taking off in the full vigor of early manhood.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fourteenth Annual Meeting, held at Boston, Mass., June 20, 21, and 22, 1892.

DR. S. W. LANGMAID, OF BOSTON, PRESIDENT.

The President's Address.—DR. LANGMAID opened his address with a touching reference to the loss of Dr. Donaldson, of Baltimore, and of Sir Morell Mackenzie—the former a Fellow, the latter an Honorary Fellow, of the Association. He then made a brief reference to the rapid advance which laryngology had made since only a few years ago, when it first took a prominent position among the specialties in medicine. He thought that our advance would be more greatly helped by faithful adherence to this Association. Companionship with fellow-workers was necessary to completeness of one's growth. Membership was not only a means of information, but it acted also as a stimulus to work. "Let us hope," he said, "that the next ten years will show such work performed that American laryngology will occupy no other position than that which has always been accorded it, namely, the first in merit as well as priority in establishment."

On the Influence of Certain Diathetic Conditions upon the Prognosis in Operations upon the Throat.—DR. D. BRYSON DELAVAN, of New York, read the paper. He called attention to the importance of discovering, before operations upon the throat, the possible existence of a diathetic condition which might influence the result of the operation, and described several such general conditions, including the strumous, the rheumatic, and the hemorrhagic diatheses, and the diseases exophthalmic goitre and general lymphadenoma. He concluded that in the case of the two last mentioned, the removal of enlarged tonsils and of adenoid hypertrophy at the vault of the pharynx was attended with no extraordinary risk. With regard to the prognosis in strumous cases, complete removal of the offending tissue is more difficult, recovery slower, and recurrence more probable. In view of the latter, patients should be warned, in these cases, of the possible necessity for future operation. Still, the earlier such cases are operated upon, the better. In rheumatic cases, no especial difficulties are offered, and the prognosis is most brilliant. The hemorrhagic diathesis is the most important, because the most dangerous. Its presence contra-indicates all surgical interference. The only known accidents that have happened in this country, in the removal of adenoid hypertrophy at the vault of the pharynx, have been in hæmophilic subjects. Adenoid enlargements are unusually common in these patients. There is no method of operating upon them, now known, that is safe. The galvano-cautery is not a reliable hæmostatic even in ordinary cases, as bleeding may occur after its use, both immediate and secondary. It should not be relied upon, therefore, in the case of bleeders. The writer urges, 1, that rigid examination as to the possible existence of the hemorrhagic diathesis be made prior to operation upon the tonsils and adenoid tissue of the pharynx in every case; 2, that in the existence of hæmophilia, operation by any procedure at present known is absolutely contra indicated; 3, that since many of these cases urgently require relief for their throat troubles, it is most desirable that a method of reaching them more satisfactory than any heretofore practised, be suggested.

Some Pathological Conditions of the Upper Air-passages Coincident with Attacks of la Grippe.—DR. S. HARTWELL CHAPMAN, of New Haven, read this paper. Beginning with November, 1891, it had been his pleasure during five months to observe certain secondary affections of the upper air-passages coincident with la grippe; and from a record of a large number of cases he had selected sixteen which were of more than ordinary interest, as the patients had previously been under treatment for other diseases from seven years to six months. Eight were cases of spinal disease, one of diabetes insipidus, four of renal disease, three of rheumatic gout. The onset of la grippe was quite similar in all these cases: headache, nausea, anorexia, flying pains, exhaustion, progressing to extreme malaise, moderate fever, pulse either considerably accelerated or greatly retarded, mild delirium, pain and stiffness in the back. He called attention to the close similarity between these symptoms of la grippe and the symptoms of the milder forms of epidemic cerebro spinal meningitis. In the rheumatic cases, the affections of the upper air-passages, during the attack of la grippe, were: in one, laryngitis crouposa, complicated with broncho-pneumonia; in two, aphthæ of mouth and pharynx, extending to the brim of the larynx. In the four cases of renal disease, the attack of grippe showed the following coincident affections: sanguineo purulent naso-pharyngeal inflammation, combined with acute tonsillitis and sympathetic enlargement of the cervical glands. The swelling of the tonsils became so great as to threaten suffocation, and was relieved by cutting. In some of them there was hemorrhage, but not dangerous; in one, croupous laryngitis. The duration of the naso-pharyngeal inflammation was about two months; of the laryngitis, only four days. In the case of diabetes, there was intense congestion of the entire pharynx and œdema of the larynx, which continued eight days and markedly interfered with breathing. During the severest period of the disease the pulse, which before had been very rapid, fell to 70, and the patient was less nervous. In one of the eight cases of spinal disease, causing humpback, a form of paralysis developed which had been absent for many years; and during the attack the pulse was reduced to 50, the normal being 80. The spinous processes were intensely sensitive. In three cases of curvature of the spine, in females, the attack of grippe was not severe, but in all there was reduction in the rate of the pulse, extreme malaise, and very sensitive spine. Secondary affections were aphonia and purulent naso-pharyngeal inflammation. Some other interesting points were also present.

DR. BEVERLEY ROBINSON, of New York, had not observed the complications mentioned by Dr. Chapman.

DR. MULHALL, of St. Louis, gave some experience with œdema of the larynx in la grippe.

Pharyngo-mycosis.—DR. FREDERICK I. KNIGHT, of Boston, had been induced to write upon this subject because of the little attention which it had received by authors in this country, hoping, he said, to draw out a discussion. Ever since special attention had been paid to diseases of the throat, observers had been struck by the peculiar obstinacy of chronic follicilitis of the tonsils, which had been not infrequently accompanied by a similar condition of the base of the tongue, and occasionally of the arches of the palate and of the pharynx. The affection consisted of whitish, yellowish, or grayish exudations, situated at the mouths of the follicles, sometimes cheesy and easily removed, sometimes cretaceous, and sometimes only tough, stringy, running deep into the follicles. There was quick recurrence after removal of the products, and even after the subsequent application of strong medicaments. Fraenkel had, in 1873, pointed out an abundance of leptothrix threads in such products, and some writers had looked upon the parasite as the cause of the condition. A number of other forms of parasitic growths in the throat had also been described. Other observers, notably Chiari, believed that the parasite was simply an accidental complication. In the treatment of typical cases of mycosis, the author had experienced the same difficulty as others, and found nothing satisfactory except boring deep into each follicle with a galvano cautery point. If any of the disease were situated in a part of the tonsil which could be excised, this would shorten the treatment.

DR. DELAVAN had found the treatment mentioned by Dr. Knight unsatisfactory, for enough of the leptothrix would remain to cause a recurrence. He had obtained

the best results from frequent washing with borax, also bichloride of mercury, and above all correction of disturbed digestion.

Dr. De Blois, of Boston, used instrumental means, also a mild astringent, as of nitrate of silver, and gave attention to digestion.

Dr. Johnson, of Baltimore, found these cases mostly debilitated school-children and old subjects. He used local and constitutional measures.

Dr. Mulhall, of St. Louis, had found nothing of any effect without treatment of the stomach.

Dr. Wright, of Brooklyn, said that these were fungi, and like other fungi would continue to grow as long as they receive the proper food.

Dr. Chapman treated these cases locally, with fuming nitric acid, introduced through a grooved platinum needle, and internally by nitro-muriatic acid.

Dr. Beverley Robinson had not seen many cases, but in one failed to effect a cure with various remedies until the patient went to Sharon Springs.

Dr. Langmaid did not object to correcting any constitutional condition, but regarded local mechanical measures necessary.

A Case of Fibrous Epithelioma at the Root of the Tongue.—Dr. Jonathan Wright, of Brooklyn, read the history of this case on account of the interest connected with the diagnosis, which was extremely difficult, and because of the rare form in which the disease presented itself. When he first examined the patient the tongue seemed normal except for two prominences on each side, at the base, which felt hard and firm. Grave doubts were entertained as to their exact nature for several months; finally, Dr. McBurney operated for cancer, but by this time an ulcer had formed which went to make the diagnosis more evident. The patient did well for a time, but finally died, without, however, a recurrence.

Report of Some Cases of Membranous Sore Throat.—Dr. Beverley Robinson, of New York, made three cases the basis of a paper on membranous sore throat. He used the term "membranous sore throat" advisedly. In the three cases reported, there was great difficulty of diagnosticating between true diphtheria and a membranous sore throat of some other origin. The bacteriological examination, however, failed to reveal the Loefler bacillus, while streptococci were present in greater or less abundance. The author pointed out the fact that failure to find the Loefler bacillus did not necessarily disprove the existence of diphtheria. He impressed the fact that a membranous sore throat of a simple character compared with diphtheria might exist, and one still be in great doubt as to diagnosis. Where such doubt existed, he claimed that it was unwise to prematurely make a diagnosis of true diphtheria, and cause the family the alarm and trouble which such an announcement would necessarily imply. At the same time certain precautions could be taken against unnecessary exposure of the well. He especially objected to sulphur fumigations. The treatment, however, might be carried out with all of the precautions which one would take in a case of true diphtheria. In this direction he spoke highly of the use of powdered cubebs, taken in small pinches into the mouth at frequent intervals. He must acknowledge, however, that the antiseptic powers of cubebs in the destruction of the Loefler bacillus had not been proven, at least outside the human body. He condemned the custom of the health officers in some sections of posting houses with diphtheria, as if persons passing such houses and not entering them were liable to take the disease.

Considerable discussion followed, and a resolution was adopted, making as a subject for discussion at the next annual meeting "The Best Means of Protecting the Public Against the Spread of Diphtheria."

Presentation of Instruments.—Dr. Morris J. Asch, of New York, presented a tampon for use after operations for deviation of the nasal septum. The tampon consisted of a hard rubber tube, with perforations.

Dr. Asch also presented a set of Dr. Dessau's antiseptic electrodes and curette for adenoid growths.

Dr D. B. Delavan, of New York, demonstrated a new method of administering iodide of potassium in cases of tertiary syphilis of the throat, where the ulceration had become so severe that the patient could not swallow with ease. The method consisted in peptonizing the milk with the essence of pepsin, in which the iodide of potassium was to be administered.

Dr. J. Wright, of Brooklyn, presented an improved forceps for the removal of adenoid growths in the post-nasal space.

Dr. John O. Roe, of Rochester, presented an improved Adams forceps for straightening the nasal septum. It possessed the advantage of enabling one to over-correct the deformity.

Dr. C. H. Knight, of New York, showed an improved snare for removal of the tonsils, with a ring-safeguard.

Intubation for Chronic Stenosis in a Boy Aged Ten.—Dr. C. H. Knight, of New York, read the history of this case. The boy was admitted to the hospital in October, 1891, and, according to the statement of his physicians, he had been ill for a week or more with dyspnœa, aphonia, cough, and fever; there was a history of bad hygiene and poor diet. When admitted, the patient could not whisper, and his breathing was quite noisy and labored. A marked feature in the case was that the dyspnœa was decidedly more marked at night; it was relieved by inhalations of oxygen. The boy's condition grew worse, and on November 8th Dr. Jarvis examined him and thought he found a neoplasm beneath the vocal bands. The vocal bands were red, and did not approximate on phonation. Beneath the cords, extending along their entire length and invading the anterior commissure, was a mass of tissue, paler in color than normal mucous membrane, having an uneven, and at certain points an almost papillated, surface. No ulceration could be discovered. The air-passage was converted into an irregular slit, so narrow as to excite surprise that adequate respiration was possible. Owing to dyspnœa an O'Dwyer tube was introduced, which was worn, more or less, for many weeks. It was impossible to get sufficient of the pathological tissue to make a satisfactory microscopic examination. Dr. Knight's first impression of it was that it was tubercular, but the absence of pulmonary signs and the marked change for the better subsequent to intubation, pointed to simple subglottic papilloma. After about three months, the boy having got along well with the tube (which was worn only part of the time), he was transferred to the surgical division for tracheotomy, thyrotomy, and radical extirpation of the neoplasm, the idea still being that it was a purely local affair. From this time the progress was rapid toward death from general tuberculosis.

The points of interest were: 1. The simplicity of intubation as compared with tracheotomy, and the ease with which the tube was extracted with the aid of cocaine and under the guidance of the mirror. 2. The slight amount of disturbance excited by the tube, and the absence of objection to its prolonged retention. Finally the question suggested itself: Was it a case of primary laryngeal tuberculosis? He believed the patient was much more comfortable than he could have been with the tracheal instead of the laryngeal tube.

Rare Forms of Laryngeal Growth.—Dr. Alexander A. MacCoy, of Philadelphia, in a paper with this title, described two cases, one of myxoma of the larynx, which had come under his care in 1888; the other of fibroma of the larynx. The former condition was quite rare; the latter not so infrequent. The myxoma seemed to have its origin from the margin of the orifice of the ventricle. The patient's voice was completely restored after its removal. In the other case, most of the growth was removed by the cold snare, and the remaining part would be operated upon later. It appeared to have sprung from the anterior and right surface of the arytenoid cartilage.

A Case of Tumor of the Larynx.—Dr. H. L. Swain, of New Haven, in a paper bearing this title, related the history of a case of fibro-myxoma of considerable size, attached by a pedicle to the anterior commissure of the vocal cords. He related the difficulties which he had encountered in removing this large growth, whose base was spread out over a greater surface than he had supposed. Its removal had been followed by relief of the difficulty connected with phonation and respiration, and the patient had remained free from recurrence two years.

Dr. C. C. Ride had found the guillotine snare more easily applied in the removal of small laryngeal growths than the forceps. He also mentioned having had syncope follow the use of four per cent. of cocaine in the throat, in the case of a policeman, recently.

Dr. Langmaid had, on the recommendation of a European author, used nicotine in operation for growth in the larynx in one case, and a very threatening poisonous symptom developed.

The Value of Sprays in the Treatment of Catarrhal Affections of the Upper Air-passages.—Dr. C. C. Rice, of New York, said that in discussing this question it was not his object to recommend the spray as a method of treatment to take the place of others. He considered the question of the use of sprays in the form of medicated oily agents, of watery solutions, of astringents, etc. While remarking upon some of the advantages of petroleum preparations, he at the same time pointed out the danger of their inconsiderate use, in that they were followed by a dry condition of the nasal passages, which was anything but agreeable. Such antiseptics as iodoform and aristol lost much of their antiseptic properties when used with oily agents, nor could their stimulating action be so well relied upon when thus used. In catarrhal affections of the upper air-passages nice judgment was required in selecting the drug, and particularly the strength of the solution to be used as a spray. The pressure used and the temperature should be adapted to the particular case, and the location to be reached by the spray. A weak solution of cocaine, say less than one per cent., was, perhaps, as good an astringent as any, and its place could seldom be taken for any purpose by such agents as morphine, aconite, etc. So far as the degree of pressure was concerned, fifteen pounds to the square inch was strong enough for the anterior nares, while twenty-five to thirty pounds was sufficient for post-nasal spray. All possible combinations could be made with cocaine, menthol, thymol, etc. By such treatment he believed that one could diminish the number of operations for nasal disease.

Considerable discussion followed, in which Dr. Bosworth, of New York, spoke rather disparagingly of nasal sprays as anything else than a cleansing measure, while Drs. Mackenzie, of Baltimore, Asch, of New York, and others, were inclined to give it a greater degree of credit.

Adenoid Forceps.—Dr. J. W. Farlow presented a form of adenoid forceps, which he had purchased in Paris, and had found an excellent instrument for removal of adenoid growths in children and adults.

The Correction of Deformity Resulting from Abscess of the Nasal Septum.—Dr. John O. Roe, of Rochester, presented photographs illustrating the results of a new method for correcting this deformity, which he had found very successful in two cases. The method adopted by Tagliacozzi, and in use at the present time, consisted in the correction of the defect by a rhino-plastic operation. A serious defect, however, in this method was the unsightly scar resulting from the operation, which was sometimes scarcely less pronounced than was the original deformity. Five years ago Dr. Roe had submitted to the profession an operation for the correction of the deformity termed pug-nose, by a subcutaneous incision, without in the slightest degree wounding the skin; and again, in 1891, an operation, equally new, for the correction of angular deformities of the nose by subcutaneous incision. At the present time he wished to present a simple method by which the deformity frequently resulting from abscess of the nasal septum might also be corrected, by a subcutaneous and intra-nasal operation. In the case detailed, after considering the various devices to accomplish this purpose without injury to the skin, he adopted the following plan: There was, as usual in these cases, marked thickening and widening of the dorsum of the nose proportionate to the amount of flattening. The thickened ridge of tissue was incised on both sides a short distance from the septum, at a point where it thinned into the ala. The incision was made along the edge of the flattened tissue through the cartilage of the ala to the under side of the skin, care being taken not to wound the latter, which was raised from the dorsum of the nose, and these flaps then turned upward and held in place by small ivory spring plates on each side, having holes through which sutures were passed from one to the other, extending through the flaps. These threads were then tied so as to hold the flaps firmly in place, care being exercised not to strangulate the part. These relieved the flattened condition of the nose, but not entirely. Owing to the entire absence of the triangular cartilage, there was not sufficient support to hold the nose upright. In order to increase the solidity of the septum, he first scarified each side of the lower portion of the septum, leaving, however, the front portion of the skin intact. He then cut wide, thick flaps from the floor of the nostril opposite the portion of the septum which he wished to render more rigid. These he turned upward and fastened together with clamps, in the manner similar to the upper flaps, and also connected the upper border of the flaps to the cut portion of the septum with fine sutures. The result was excellent. To maintain the nose in position until the parts healed he used a small spiral spring.

The After-results of Nasal Cauterization.—Dr. T. A. De Blois, of Boston, read the paper. Owing to the difficulty of tracing patients upon whom operation had been performed which may not have proven ultimately successful, he gave the history of five or six in which he or others had cauterized the nose two or more years previously. In most of them the cauterization had been for an hypertrophied condition of the turbinated bone, and the immediate result, as far as relief of the symptoms was concerned, had been more or less successful. Two years subsequently the patients had returned, again complaining of nasal obstruction. A rhinoscopic examination had shown in some, on either side of the original scar left by the cautery, a swollen and projecting mucous membrane which blocked up the nasal passages. In another case, a somewhat remarkable one, the mucous membrane, which was thrown in corrugated folds, had been cauterized frequently at different hospitals. Some of these cases, and doubtless many others walking the street, showed that the cautery might fail of the desired effects by improper application, such as, on the one hand, making the scar tissue too deep, or, on the other, too shallow; and, again, of extending it through too great a distance or not far enough.

A somewhat lengthy discussion followed, which was devoted mostly to the immediate results of bad usage of the cautery. The efficacy and safety of this method of treatment, in cases to which it was adapted, was dwelt upon by Drs. Wright, Langmaid, Mulhall, and others.

A Case of Suppurating Ethmoiditis.—Dr. J. H. Bryan, of Washington, related a history of a case of suppuration of the ethmoid cells, terminating in caries, and illustrating the condition described as rhinitis caseosa. The patient gave a history of having suffered from caries of an upper molar tooth. In July her nose became closed, the secretions, at first watery, became thick and fetid. There was a pain over the bridge of the nose, extending along the infra-orbital ridge to the temporal region. Severe headache, pain on pressure of the eyeball, crepitating sensation under the orbit. On the left side of the nose were seen two mucous polypi attached to the anterior extremity of the middle turbinated bone.

After snaring off the polypi, the thick caseous secretion was observed to come from both the middle meatus and from above, between the middle turbinated body and the septum. Examination with the electric light showed the left antrum to be opaque, showing this to be complicated with the inflammation of the ethmoid cells. In spite of treatment the condition grew worse, until, on her way to his office, the abscess discharged spontaneously a great quantity of thick caseous secretion, after which the pain ceased and general health improved. The complications of suppurating ethmoiditis more frequently met with were abscess of the antrum, abscess of the orbit, and meningitis. In the above case, the antral complication was purely accidental, dependent upon a carious tooth.

Election of Officers.—*President*, Morris J. Asch, of New York; *First Vice-President*, S. Johnston, of Baltimore; *Second Vice President*, J. C. Mulhall, of St. Louis; *Secretary and Treasurer*, C. H. Knight, of New York; *Librarian*, T. R. French, of Brooklyn; *Member of Council*, S. W. Langmaid, of Boston.

Place of next meeting, New York, last week in May.

Correspondence.

THE HEALTH RESORTS OF THE RIVIERA

(Continued from p 616.)

VII.—Monaco and Monte Carlo.

(From our Special Commissioner.)

THE PRINCIPALITY OF MONACO—MONACO PROPER, LA CONDAMINE, MONTE CARLO, LES MOULINS—SITUATION AND POPULATION—BEAUTIFUL MONTE CARLO—THE CASINO AT MONTE CARLO—A CHAPTER ON GAMBLING—MONTE CARLO AS A HEALTH-RESORT—THE MOST FREQUENTED STATION ON THE RIVIERA—WINDS, TEMPERATURE, AND RAINFALL—A CLEAN CITY—OLD CESSPOOLS AND OTHER IMPERFECTIONS OF DRAINAGE—THE DRINKING WATER UNPOTABLE—TYPHOID FEVER AND OTHER DISEASES; THE COMITÉ D'HYGIÈNE—MEDITERRANEAN SORE THROAT—THE CASINO DISEASE—WALKS, DRIVES, AND EXCURSIONS—CAP. MARTIN—THE RIGI D'HIVER—THE BATHING ESTABLISHMENT—THEATRICALS AND CONCERTS.

Going eastward from Beaulieu, we pass the stations of Eze and La Turbie sur Mer. On the heights above are old Eza, once a stronghold of Saracenic plunderers, and Turbia with its famous tower, erected by Cæsar Augustus, which even now remains a picturesque ruin. Both are highly interesting places to visit, but neither of them are recognized winter health resorts. We now reach Monaco. This is the capital of the smallest principality in Europe, if not the whole world. Monaco is also the oldest established European dynasty, the reign of the Grimaldi going back in the direct line to the twelfth century. The Princes of Monaco were little better than robbers and pirates, down to the close of the eighteenth century. And modern Monaco, deriving its chief éclat from the famous gambling-tables at Monte Carlo, it is not a far fetched simile which likens the method by which the last scion of the ancient house of Grimaldi obtains his princely income to that in vogue during the reign of his forefathers. It is an interesting political-geographical anomaly that the dominions of this petty Prince of Monaco are now entirely within and, to a certain extent, under the protection of republican France. Yet the Prince is an autocratic ruler in his own territory, which looks about as big as Central Park, and is, perhaps, one-tenth the size of the Bois de Boulogne in Paris. The total area of his empire is barely two hundred and fifty acres. But still he insists on maintaining, in a liliputian way, the entire pompous rigmarole characterizing the court life of the most potent monarchs of Europe. He treats them as equals, and is in turn treated on the same exalted footing.

From the American point of view, nothing more amusing could readily be found than the elaborate copying of established royal forms and fashions in this miniature monarchy on the little rock of Monaco. The Prince sends his ambassadors to foreign powers; he has money coined with his own image; postage-stamps bearing his features are used by his loyal subjects; he has a standing army, mustering forty-eight men, with a war footing amounting to six extra heads; he has a Governor general, who rules during his frequent absences; he has judges and policemen; he has an established church with a real bishop at its head; he supports a Chamberlain, a Grand Almoner, a band of secretaries, ornamental attachés of every kind, and scores of other functionaries and dignitaries, who are considered essential furniture in every royal household, and who, like our own politicians, are always on hand on pay-day.

It has been observed that the etiquette of his court is of the most rigorous type, that his castle is a little wonder, and that his art collection is one of the best which exists. In this country, so blessed by Providence, the Finance Minister has nothing whatever to do, for the simple reason that all taxes have been abolished. The Minister of War finds it impossible to take active action, for his infantrymen are only cognisant of two drills—those of presenting arms to the Prince and of firing at the fishes, and yet whenever a new recruit is captured the poor fellow is almost drilled to death by his numerous superior officers. The Minister of Marine has only one duty, that of seeing that the twelve sailors of the Prince's yact are ready to go to sea when needed. The Minister of Public Works has no work to do, because the public property is only composed of a garden and three streets. The busiest of all officials is the Minister for Foreign Affairs, whose duty it is to assure all the powers that the prince has no intention of troubling the peace of Europe.

Perhaps it is proper for me to mention in this connection that the Governor of Monaco kindly supplied me with considerable information concerning this place. But I have naturally not relied on his statements alone, as they can scarcely be regarded otherwise than *ex parte* views For instance the Governor strenuously maintained that it was the large private fortune of his sovereign which permitted that exalted person to be so lavish in regard to the expenditure necessary for maintaining the principality in such splendid style. But as the Prince does not hesitate to pocket the enormous annual revenue guaranteed him by the Casino, in which, moreover, he is a secret shareholder, and inasmuch as he has stipulated in the new contract that he must be paid a percentage of all profits in excess of a fixed limit, and finally since it is well known that he does not spend on his principality one tenth of the money turned over to him by the gaming-tables, I feel constrained to differ slightly from that highly courteous gentleman of the old school, "Son Excellence M. le Baron de Farincourt, Gouverneur général de la Principauti de Monaco," late prefect under the third Napoleon. It is doubtless literally true that all the officials of the Prince are on his pay-roll. But as the Casino pays the Prince, there is no mystery about the actual origin of the money.

Small as it is Monaco consists of four parts, although the many new buildings recently constructed and still springing up have now practically obliterated the old dividing lines. First there is Monaco proper, on the famous rock, which runs some two hundred and fifty yards out to sea, and rises precipitously almost two hundred feet above the level of the water. Secondly you have the Condamine, the newly built business section, almost enclosing an attractive littte harbor of horseshoe shape. La Condamine is almost level with the sea. Then comes Monte Carlo, on a bold headland, joined westward by the former, and eastward by the fourth division, known as Les Moulins.

Monaco is only about nine miles in an easterly direction from Nice, and some six miles westward from Men-

tone. The principality forms a narrow strip of land running along the shores of the Mediterranean, and somewhat resembling an axe with a curved handle, the blade representing Monaco proper. The French communes of La Turbie and Roquebrune, formerly belonging to the Grimaldi, now mark the eastern and western limits of the principality. Its permanent population is about twelve thousand, but is rather rapidly increasing, possibly because the subjects of the prince are entirely exempt from military duty and taxation. The Casino alone gives employment to about one-tenth of the entire population of the principality. This Casino is the gaudy gambling-palace belonging to a stock company called the "Société des Bains de Mer," and is named by courtesy, and in books, the "Cercle des Etrangers."

It is impossible to convey any just idea of the first impression produced by the sight of Monte Carlo, that beauty-spot of the Mediterranean littoral. Prepared as you may be by the apparently endless succession of picturesque views, that greet you at every turn in these unrivalled regions, you are nevertheless fairly staggered by the astonishing vista unfolded before you, as the dazzling splendors of Monte Carlo first burst upon the eye. For the moment you are held spell-bound by a scene that, later on, seems nothing short of theatrical in its carefully studied effects. Give your imagination full swing and you will yet be unable to improve on what nature and art combined have here provided to feast the sense of sight. A second, a third, and all succeeding visits only serve to accentuate some particular point of attractiveness as regards the artistic arrangement of color, outline or perspective, in a picture that has been so often painted and described as to be now a sadly hackneyed subject for both pen and brush. Nevertheless the new-comer can never quite resist the temptation to exhaust his entire reserve stock of superlatives in the fruitless endeavor to do justice to the fairest of fair places. For where else can you find such groupings of bold bare rock jutting far out into the blue green of a billowy sea? In days of calm the Mediterranean seems a luminous expanse of rare turquoise that breaks in foamy fringe of white on the shoreline. But let it storm, and a surging surf tosses its angry waves against the beetling crags, whence a fretful spray is flung high up into the air and falls in a crystalline shower back into the mother lap of the seething ocean. On the rocks the never-ending contest of centuries has smoothed many a harsh outline down to softness. But that is all. The headland budges not. Its warm-hued ledges, so fantastically shaped, frown down forevermore upon the impotent rage of warring waves. Look landward now! Where can you gaze again upon so rich a foreground of carefully cultivated tropical plants luxuriating in sun-steeped gardens. Go one step beyond and a tangled mass of wildest heather, aloes, prickly pears, and countless other shrubs confronts you.

In what other land will you have all this bounteous verdure set off against a near background of steeply rising cliffs, intersected by weird and shadowy ravines? And then the vivid contrast of the wooded slopes, thickly studded with palms and evergreens, with locusts and with olives, while everywhere the white villas gleam and glint, burnished by the fierce light of a golden sun. It seems too much for mortal sight, and the eye rests gladly at length upon the dull gray monochrome of the higher mountains, or searches quite beyond where it knows snow-clad Alps rear their monarch heads high up into the deep azure of an Italian sky.

As you wander about in this land, glowing in the cloudless light, even common objects seem as if transfigured into things of radiant beauty. At every step orange and lemon groves temptingly greet you, many-colored butterflies dance through the perfumed air, a few startled birds flit hither and thither, myriad roses are in full bloom, a vagrant breeze wantons in quivering foliage, the distant surf languidly mumbles its lullaby. Every sense is appealed to in a symphony of delight. And all this happens in mid-winter, when any train will carry you in a few hours to a snow-bound landscape.

Call it a terrestrial paradise, a scene from fairyland, a day-dream, or anything you like. Yet the bitter fact remains that, as it stands to day, it is in truth but a poetical prelude to the cynical prose of a gambler's gilded palace.

There it stands, that showy building, a mockery to all. For we each and everyone of us contribute, at least once, to maintain it in all its gaudy iniquity. Personally I have no kind of sympathy with that narrow minded, hypocritical perverseness which upholds all kinds of disguised and private gambling, while openly denouncing as ultra-vicious the only public den at beautiful and seductive Monte Carlo.

But gambling is gambling, and we might as well look this social evil straight in the face. We will then be forced to admit that more real gambling is done in the United States, and elsewhere too, for that matter, than at fifty Monte Carlos.

Curiously enough, recent issues of our leading magazines all deal with this question. And as no Monte Carlo article would be considered complete without a reference to this evil, I cannot do better than give a few quotations. The writer in the *North American Review*, February, 1892, starts in this way: "What the Louisiana Lottery Company is doing for the State of Louisiana by corrupting officials, bribing public servants, destroying public morals, breeding crime and dishonesty, wrecking homes, and impoverishing the laboring classes, the pool gamblers of New York and New Jersey are doing for these two States."

Regarding Uncle Sam's liberty-loving children we are told: "This nation is fast earning an unsavory reputation because of gambling propensities. Moral and religious influences seem to have no effect in checking this degrading passion. Year after year the gambling fraternity are becoming more and more strongly intrenched, while continued success renders them more and more arrogant and unscrupulous. Political leaders in both the Republican and the Democratic party, in localities where gambling is especially carried on, appear to be hand in glove with the principal 'boss' gamblers. Coming down from the halls of legislation, this dishonest and piratical crew enter the halls of justice and demand that the laws shall not be enforced against the members of their various fraternities. The hands of prosecuting attorneys are fettered by the command of political 'bosses,' or corrupted by the 'hush-money' of those who grow rich by violating the laws of the land. Underneath the surface, hidden from public view, there seems to be a positive understanding between political leaders and gambling 'bosses' that if the gambling 'bosses' pay liberally of the funds dishonestly taken from others, in support of local politics, the members of the fraternity so paying shall have immunity from interference or punishment by public officials.

"The demoralization flowing from these schemes has entered the marts of trade, honeycombed commercial institutions, and undermined the stability of banking corporations. Our young men are rendered dishonest, and ruined by thousands each year. Defalcations, embezzlements, forgeries, thefts, robberies, breaches of trust, suicides, and murders are breaking out in our midst as the harvest of this seed-sowing."

It ill becomes an American to lift his hands in holy horror at wicked Monte Carlo, if the above represents but a tithe of the actual truth.

Again, apropos of the Louisiana lottery, that has only quite recently received its quietus, Mr. Hale says (*The Cosmopolitan*, February, 1892) that "gambling is bad enough anywhere, but to carry gambling to the door of every hovel and attic, to invite the very poorest people in the country to engage in gambling, by the attractive and seductive hope that great wealth will come of a sudden, is to break up by the State itself habits of industry and thrift. It is to say to people, 'You shall not even

be at the pains of going to a gambling-hell. You need not even take the time to study the intricacies of *rouge et noir*. We will do your gambling for you. You shall press the button and we will do the rest.' Now there needs no argument to show that a State or a nation which is undertaking to suppress gambling is belying its own words if at the same moment it creates an elaborate and attractive system of gambling, and gives to it all the dignity which belongs to an arrangement sanctioned by law."

Finally, Mr. Buel, in *The Century*, also for February, 1892, makes use of some pretty plain language. "We as a people," he says, "have a growing courage of our gambling propensities." The memory of Thomas Jefferson is invoked, as he might be interested to see how large a part the wheel of fortune plays in our present "pursuit of happiness." "As a lover of democratic equality, he would see tens of thousands mingling amicably in 'exchanges' of different sorts where no particular gamble is raised above any other gamble; where the old and the young, the affluent man of success and the young clerk or messenger-boy just beginning his business life, make their bets on the results of horse-races, or base ball games, or pugilistic encounters, or even on the outcome of the American citizen's proud exercise of the right of manhood suffrage. As a maker of laws he would be amused to learn that the laws of the land are opposed to all these practices, which nevertheless are carried on openly because the hearts and souls of the people cry out for them. As the founder of a university he would speculate on the importance of athletic contests in our college life, and observe, if he had half an eye, that nine out of ten of the students also speculate on them. As a one-time advocate of a national lottery, he would be interested to know that the yearly proceeds of the Louisiana Lottery have grown to be twice as large as the revenues of the United States in 1800. The Louisiana Lottery is the most important training-school we possess for the higher gambling institutions of our grand republic. It is the kindergarten, so to speak, in which the happy school boy or the luckless orphan may bet the dimes he has hoarded, begged, or stolen; and it is the sequestered sanctuary where the frugal housewife or the lone widow may also drop her nickel in the slot and cause the wheel of fortune to revolve for her. It is after this manner that lotteries do good by stealth. And let no purse-proud statesman who will not be beggared if he lose his political wager, nor any well-to-do citizen who thinks the thrill of losing a thousand dollars on a horse-race is worth all it costs, nor the gentleman who enjoys the sedentary amusement of 'bucking the tiger,' presume to take from the poor their cherished game of chance! The profligate rich have ever been ready to resent the so-called pernicious amusements of the poor!"

It seems needless to go on multiplying quotations. But this much may be said: When we have driven the scourge of gambling from our own shores, when we have purified the nation of its gambling instincts, it will then be time enough to tell the Prince of Monaco that he ought to follow suit and shut up his gilded den. But for the present we can save all our eloquent thunder for home consumption. And for the information of those who have supposed that by influencing public opinion through their writings the Prince might be induced to stop the game, I will state that he has not the remotest intention of so doing during the remainder of his natural life, no matter what may be said, thought, or written by outsiders.

After this digression we will turn to more strictly medical subjects, although every physician on the Riviera well knows that Monte Carlo gambling has decided pathological bearings, and is directly responsible for many serious departures from health, in addition to certain sudden departures of a different kind.

There is no doubt that this place has recently become a favored residence of invalids, who are attracted solely by its advantages as a winter health-resort. My experience on the Riviera enables me to state as a positive fact that many more people go to Monte Carlo to gamble from the various resorts near it than from the town itself. Cannes, Nice, Mentone, and even San Remo, send their daily quota of gamblers there in uncomfortably crowded trains. And those who have no inclination for the silly game may just as well live within a stone's throw of the building itself as miles away. I cannot, therefore, quite agree with those who would warn people away from Monte Carlo merely on account of the gambling going on there. If they are so weak as to have to yield to this particular temptation, they are better off at home than on the Riviera. It has seemed to me, however, that Americans are abundantly able to take care of themselves wherever they may happen to be. It was necessary to state my views on this point, because I believe Monte Carlo could be made one of the best winter stations on the whole coast. Even now every possible accommodation is offered there, and the only criticism one can justly make on that score is that the hotel and restaurant rates are often exorbitant. But if it is not a cheap place, it certainly can claim to be a good one, at least so far as the provision of American comforts and luxuries is concerned. This is considerably more than can be said for some other winter stations that are scattered along the coast here.

As already intimated, all Riviera roads lead to Monte Carlo. Even the road to ruin runs a prosperous branch-line down to that charming spot. Indeed "wintering on the Riviera" means for many people, whether of high degree or low, whether actually rich or only willing to rapidly be so, whether severely virtuous or equally otherwise—wintering on the Riviera means for a motley crowd of thousands of visitors "bucking the tiger" on the green cloth of the most famous gambling den of modern times. It is small wonder, therefore, that "the company" secures an annual booty from the numerous flock of casino frequenters amounting to some eight to ten millions of dollars. And it is not at all surprising to hear that an enterprising American company is anxious to start an American Monte Carlo in Lower California. They certainly have an excellent climate down there. But I am not so sure that they could draw enough native fools to the place to make it pay. Besides we have our Wall Street, and can manage to worry along without an imitation Monte Carlo.

Monte Carlo is one of the warmest winter stations on the coast. But it is not true that it enjoys a more equable temperature than all other resorts. Sudden thermometrical variations occur there just as elsewhere on the Riviera. Some parts of the principality are very well protected from winds, while others are decidedly exposed to them. The bare rocks rising up to a considerable height, immediately back of Monte Carlo, afford ample protection from cold northerly winds, and by reflecting the sun's rays appreciably raise the temperature in their vicinity. But when the sun has set the succeeding chill is felt all the more violently, though the actual fall of temperature is less abrupt and less perceptible than our sensations indicate. It would occupy too much space to go into details here concerning the physical configuration of the various sections of the Monégasque territory, but the reader may infer from these general indications that some well-sheltered and warm nooks can be found at Monaco. For well-to-do invalids the place will doubtless be made increasingly attractive, on account of the large sums of money spent annually for improvements. But people don't save money by going there, even when they gamble and win. The rainfall and the proportion of sunny days to cloudy ones are about the same as Nice or Mentone, and need not be separately considered. One advantage in favor of Monaco is that less dust is found there than at Nice, Cannes, or Hyères.

All Monaco, excepting a few alleys in the older quarters, is undeniably kept in a condition of admirable

cleanliness. The paving is in good repair, the roads are not very dusty, frequent sweepings and flushings impart to every street a look of trim neatness that offers a marked contrast to the neglected state of some other Riviera resorts. Yet surface cleanliness is only one factor conducive to healthfulness. In some respects Monte Carlo is more dangerous than dirtier towns.

Excepting the low lying quarter called Condamine, Monaco affords every natural advantage for a perfect system of drainage. Yet so far from being in good shape, this essential sanitary requirement leaves much to be desired here. It is true, drains have now been established in all the principal streets, and most of them have a sufficient natural incline. But, as elsewhere on the Riviera, the house connections are insecure and dangerous. This applies more particularly to the old house-pipes that were subjected to the violent shaking up of the earthquake a few years ago. The authorities are only just beginning to realize that, in spite of the prevalent English closets, some radical reforms may be needed.

Many of the old, poorly constructed, unventilated cesspools still exist, and receive the house soil. As plenty of water is now used they would have to be emptied every two or three weeks. But house-owners, in order to avoid this expenditure, have, in spite of forbidding law, connected their cesspools by overflow pipes with the main sewers. Cut off traps having been quite generally omitted, the obvious consequence is that sewer gas is almost certain to enter all hotels, villas, and lodging-houses provided after this obsolete fashion. The evils of so reckless a system are to some extent counteracted by the winds that cleanse the polluted atmosphere. But the night-air of such dwellings is bound to be dangerous, and, whenever possible, windows ought to be kept open all night. I am bound to state, however, that offensive odors, such as are so often justly complained of at Nice, are only rarely experienced at Monte Carlo. But Nice is eight times the size of Monaco, as regards population, and as the latter place grows, the present evils are sure to augment, unless proper precautions are taken.

The sewers, intended only for surface waters, now discharge into the landlocked little harbor, which is an additional nuisance, fraught with potential danger for this place. But to my mind the chief menace to health at Monaco lies in the fact that the authorities, in place of frankly admitting the present insecurity of their town, stubbornly refuse to see that anything short of perfection is to be found there. Unless a more modern spirit comes over them, they will some day have reason to regret this ostrich-like stupidity and obstinate optimism. English sanitary engineers have lately issued documents certifying the good condition of most of the larger hotels. The plumbing of some of the new houses is also good. But apart from that, things are as stated above, *i.e.*, unsatisfactory and unsafe.

A branch of the open canal la Vésubie, already described in connection with Nice, conducts the water from that town to Monaco. Exposed as it is to all kinds of contamination this water cannot be considered potable before having been subjected to the double processes of filtration and boiling. This is so well known at Nice that there the Vésubie water is only used for street-cleaning, sewer flushing, and other municipal purposes. But the Monégasques believe in the purity of this water and seem to drink it without detriment to their health. Of course that is no reason why a foreigner should indulge in what to him might prove a costly experiment. It is satisfactory to know, however, that the authorities are looking for better water.

Through the courtesy of the Chevalier de Loth, the United States Consular Agent at Monaco, I was allowed to examine the source of a new water-supply for the principality. It is a rather curious one. Situated at no great distance in an easterly direction from the Casino, and quite on a level with the sea, some limestone ledges abut on a little strip of sandy beach. It is here that limpid, sparkling, spring water has been found to well up out of the rocks. The work of constructing iron conduits and pumping the water up to the level of the town is already well under way. But I am unable to say anything about the composition of this water, beyond repeating the assertion of our consul that several analyses have shown it to be pure. It ought to be a very hard water, however, and it did not strike me that this single source would be likely to prove sufficient for the growing needs of the town. The true source of this spring is thought to be some subterranean reservoir that discharges its surplus through crevices in the rocks. If that be so, it would at least insure a permanent freedom from organic contamination, which the Vésubie water now employed cannot boast of.

There is no doubt that Monte Carlo is not free from typhoid fever. Every effort has been made to cover up this fact and keep it from the public. Even local physicians have not scrupled to lend their aid to this foolish policy of concealment, which never pays in the long run. Still, nothing in the shape of an epidemic has visited the place for several years past. And as a general rule zymotic diseases are neither of frequent occurrence there, nor do they, when encountered, readily assume a virulent type.

But hotel-keepers and other interested parties have not yet cared to learn the necessity of energetic disinfection of contaminated premises, furniture, bedding, etc., and this, despite the existence of a formidable bureau called the "Comité d'Hygiene publique et de Salubrité," with the Governor-general for its president. This board of health has been truthfully styled a mere farce by one of the most prominent British practitioners at Monte Carlo.

I regret that I am unable to present to the readers of the RECORD a study of vital statistics, and other authentic data concerning the health of the natives. The authorities have failed so far to keep their promise to supply this information, and the foreign physicians whom I consulted were quite in the dark, because they are refused access to the official records. But in a general way it can be safely said that, in spite of the occasional occurrence of typhoid fever at Monaco, the place is just at present healthy enough, the dangers I have alluded to being potential rather than actual.

It is estimated that half a million visitors now reach this place every year. Of course the vast majority of that number are mere recurrent or transient gamblers, who enter no other building than the Casino. Still the foreign winter colony is now said to be up in the thousands. And if Monaco were really the pest-hole that some persons who ought to know have informed me it is, even the autocracy of Monégasque officials could not have kept the truth from leaking out. As I have pointed out, there is enough room for improvement. But to exaggerate either the actual drawbacks, or underestimate the possible advantages of Monaco, would be equally unjust, and foreign to the purposes of the RECORD mission.

Febrile attacks accompanied by sore-throat are of frequent occurrence here, but they are not peculiar to Monaco, and rarely cause more than temporary annoyance. One attack does not at all confer immunity from subsequent ones. The malady is an ordinary smart tonsillitis, and scarcely deserves to be called "Mediterranean sore-throat," except by reason of its wide distribution and prevalence along the whole coast.

A worse place than the Casino, with its dusty, stifling, absolutely unventilated rooms, cannot be found for persons with a tendency to throat troubles. But even perfectly healthy people invite sickness there, especially by frequenting the gambling-tables in the evening hours. The Monte Carlo physicians have not yet coined a word for the most frequent local disease, although they must know it as a distinct pathological entity. I may, therefore, be permitted to enrich medical terminology by supplying the omission. The morbid state in question may be called "Maladie du Casino." It is characterized by headache,

depression, anorexia, the latter sometimes accompanied by nausea, restlessness leading to insomnia, misanthropy, and constipation. When seen in its early stages, change of climate promptly leads to recovery. But if not treated in that way, a worse state will surely follow, and may then seriously endanger the patient's prospects of a cure. The incidental depletion of the financial system is a frequent complication difficult to relieve, except by gold treatment.

Some fine roads now lead through lovely scenery to the near-by places. Yet people apparently grow lazy here, and the roads are often all but deserted. Favorite excursions are those on the upper and lower Corniche roads to Nice, to La Turbie, Eze, Roquebrune, or Mentone.

The drive to Cap Martin is also a pleasant one, and has become very popular since the advent there of the Prince of Wales, the ex-Empress Eugénie, and other aristocratic attractions. Cap Martin is the name given to a tongue of land that juts out to sea to the east of Monaco. It is thickly wooded and until the spacious new hotel was built there it was known only to enterprising picknickers and pedestrians. It is very much exposed to winds, but as most of them are tempered by having crossed the sea, it is less objectionable on that score than might be supposed.

Although quite a new resort with only one hotel it has already become a decidedly popular and much frequented one. Some fine private villas are soon to be built there. And it is hoped that in view of existing restrictions it will remain a small and exclusive place.

Walking at Monte Carlo can only be recommended to those who are able to combine climbing with their pedestrianism.

Under the auspices of the "Compagnie du Chemin de fer à Cremaillière d'interêt local de la Turbie," a new enterprise is soon to be launched. I am able to state, on the authority of the Governor of Monaco, that the plans are now complete for constructing a cog wheel railroad to run up a steep hill to Turbia from Monaco station. This will be sure to prove a great attraction here, as the view from Turbia is one of the most beautiful ones in all this picturesque region. Work is to be begun this summer and the road is supposed to be in running order in about one year. The rather ambitious name of Winter Rigi has been chosen for the mountain. Several other improvements are also in contemplation, but as they are not yet definitely decided upon I omit their mention.

The bathing establishment is expensively built and is situated at the Condamine. It is too much in the shade for winter open-air bathing, and its hygienic condition is unsatisfactory. In summer time it may be useful, but Americans do not frequent Monte Carlo at that season.

It may be mentioned en passant that the Casino provides excellent theatricals and music, and gives a classical concert once a week (free admission) which is not surpassed anywhere on the Continent. Of course this is a mere sop to the gambling fraternity. The lack of ventilation in the always overcrowded gaudy theatre is simply disgraceful. Apart from this no wholesome amusements are provided, all interest being centred in the gaming tables. If the authorities really and seriously contemplate making a winter sanitarium of Monte Carlo, in addition to retaining the dubious prestige of possessing a world-renowned "Casino," they will have to bestir themselves. There can be no lack of funds to do everything in the most approved manner. And judicious expenditure in that direction is never wasted. Monte Carlo can be made a real health resort, and that must be my excuse for having given so much space to this much-abused place, which most medical writers have treated so gingerly that its name is barely mentioned among the Riviera health resorts.

International Dermatological Congress.—The second Dermatological Congress will be held in Vienna from September 5 to 10, 1892.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 16, 1892.

	Cases.	Deaths.
Typhus fever	3	0
Typhoid fever	16	8
Scarlet fever	78	8
Cerebro-spinal meningitis	5	13
Measles	270	23
Diphtheria	64	21
Small-pox	11	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Leprosy in the Caucasus.—In a paper read before the Caucasian Medical Society, Professor Minkh gave a history of leprosy in the Tersk district. He showed that it must have been in existence there among emigrants from the borders of the Don and of the Volga during the latter part of the last century, and that though there are no statistics of the number of persons affected up to 1840, it must have been appreciable, as there were lazarets in a good many places for lepers. From 1841 to 1883 the disease seems to have been steadily on the increase, but after that the number of victims rapidly diminished. It is an interesting fact that in localities where lepers were kept apart from healthy persons in special buildings the numbers attacked diminished, while in other localities where segregation was not practised they increased.—*The Lancet.*

Insanity of a Professional Faster.—Succi, the Italian faster, whose feats of long abstinence from food have made him notorious, has gone mad and is now an inmate of an asylum in Paris. He attempted to give an exhibition not long ago in London, but broke down, and the disappointment of his failure seems to have lighted up the already kindled flame of mental disease, the first symptoms of which became apparent during one of his fasting performances in Florence some four years ago. After his failure in London he went to Paris, and there was arrested one evening while creating a disturbance on the Boulevard des Italiens, proclaiming noisily that he was the mighty Cæsar.

Superiority of Medical over Clerical Missionaries.—Year by year, as the General Assemblies of the Scotch Church meet, the subject of foreign missions is dealt with. Annually, also, the account of the spiritual benefits conferred are calculated to afford amusement to the impartial reader. We are afraid to say how much each convert costs; the annual number rarely exceeds one or two at the different stations. From many of the missions, indeed, those in charge are perforce compelled to tabulate the number of "inquirers," having no real converts to announce. On the other hand, the reports from the medical side of these missions is much better reading. To take the case of the mission carried on by the Church of Scotland in Smyrna. Two Jews were baptized, one of them evidently in the habit of being so converted, during one year, while the doctor attached to the station treated one hundred and twenty eight patients in the hospital, made eight hundred visits, and altogether, counting his dispensary work, saw about four thousand five hundred cases, most of whom were Jews. As the medical man has to read the New Testament to his in-patients and preach to the out-patients once a week, his office, we imagine, can be no sinecure. In the report it is noted that many of the cases were surgical, requiring operations, and that all those operated on did well. Each convert cost £210, each patient, including those in hospital, 12s. 6d. —*Medical Press.*

DIPHTHERIA AND ALLIED PSEUDO-MEMBRANOUS INFLAMMATIONS—A CLINICAL AND BACTERIOLOGICAL STUDY.[1]

BY WILLIAM HALLOCK PARK, M.D.,

NEW YORK.

THE diagnosis of diphtheria has always been a subject of extreme importance in medicine.

Are all cases of diffuse pseudo-membranous inflammation of the upper air-passages, and all cases of membranous laryngitis, rhinitis, and tonsillitis the local manifestation of one disease—diphtheria? Are all these cases equally contagious and equally dangerous? These are questions which occur daily to the minds of practitioners.

The marked differences noticed in different cases have always forced on physicians the possibility that, under the term diphtheria, we may include more than one disease. When it was discovered that two different conditions existed in pseudo-membranous inflammations it was hoped that here we had a reliable diagnostic sign. One is a gangrenous inflammation, in which there is superficial necrosis, leaving on the removal of the adherent pseudo-membrane a bleeding surface; the other is an exudative inflammation, leaving on the removal of the loosely attached deposit an intact surface. The first was supposed to occur in true diphtheria, the second as a result of some local irritant, either chemical or bacteriological. Experience proved this test, like so many others, unreliable, and most clinical observers still thought it wisest to consider all pseudo-membranous inflammations as if they were the local expression of the acute infectious disease which we call diphtheria.

Since the discovery of the existence of bacteria, and of their relation to disease, a new hope has arisen that by the bacteriological examination of these pseudo-membranes we might get a truer knowledge of the disease called diphtheria, and settle the question, whether or no, under this name we should include more than one disease. At the outset the difficulties were very great, owing to the multitude of bacterial forms present in the mouth. However, persistent investigation, aided by the improved methods of bacteriological study, has overcome all these obstacles.

Although recent reviews by Loeffler,[2] Welch,[3] and others makes it almost unnecessary, it is thought best, in order to have the whole subject fresh in mind, to give as briefly as possible the reasons which have led to the acceptance of the Klebs-Loeffler bacillus as the cause of true diphtheria, this sketch to be followed by a summary of the chief characteristics of the bacillus, and the more important lesions produced by it. Finally, to present the evidence that a streptococcus is the most frequent agent of infection in cases of pseudo-membranous inflammation in which the Klebs-Loeffler bacillus is absent.

True Diphtheria.—In the year 1883, Klebs[4] demonstrated, morphologically, the constant occurrence of a bacillus in the pseudo membranes of those subject to epidemic diphtheria. Loeffler,[5] in 1884, published the results of a very thorough and extensive series of investigations. He found the bacillus described by Klebs in the pseudo-membranes in nearly all cases examined. He proved by inoculating that this bacillus was pathogenic in certain animals. When inoculated on the injured mucous membrane it produced a pseudo-membrane somewhat like that present in human diphtheria. He failed to find the Klebs bacillus either in the blood or organs of fatal cases of human diphtheria, or in the same regions of animals dying after inoculation. He came to the conclusion that the Klebs bacillus was the probable cause of true diphtheria. He considered, however, that further investigations were necessary to prove his conclusion.

Since then the whole subject has been examined with great care, not only by Loeffler himself, but also, independently, by a large number of investigators, both in Europe and America. The work of Roux and Yersin,[1] in Paris; Loeffler, in Berlin; Kolisko and Paltauf,[2] in Vienna; Ortmann,[3] in Königsberg; Zarniko,[4] in Kiel; Escherich,[5] in Munich; Beck,[6] Brieger,[7] and Fraenkel,[8] in Berlin; Tangl,[9] in Tubingen; Babes,[10] in Bucharest; d'Espine,[11] in Geneva; Klein,[12] in London; Welch and Abbott,[13] in Baltimore; Prudden,[14] in New York, and many others, has established that in all cases of typical infectious diphtheria the Klebs-Loeffler bacilli are present in large numbers in the pseudo-membranes, either alone or associated with other bacteria, and that the Klebs-Loeffler bacilli in all other inflammations of the throat and in healthy throats are very rarely found.

Pseudo-membranes, paralysis, and organic lesions can be produced in inoculated animals, similar to those found in human diphtheria. A toxine is produced by the bacilli which, when isolated and inoculated, produces the same results, with the exception of the pseudo-membrane, as the pure cultures.

All the conditions have now been fulfilled which are necessary to the proof of the dependence of true diphtheria upon the bacilli described by Klebs and Loeffler.

The Klebs-Loeffler Bacilli.—They are moderate-sized rods, usually slightly bent, averaging nearly as long as the tubercle bacilli, but twice as broad and usually with rounded ends. According to the rapidity of growth, the soil, and other conditions, the form and size of the micro-organisms varies, and the differences are striking in appearance. The bacteria are sometimes enveloped in a more or less capacious membrane; sometimes the contents divide into a number of pieces, separated by transverse divisions; one end of the rods is frequently thickened like a club, or both ends may be clubbed, or one or both pointed. The bacilli are immobile and have no spores. The best staining agent is Loeffler's alkaline methyl blue. Some forms stain uniformly, others in vari-

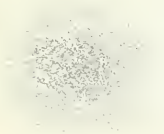
ous irregular ways, the most common being the appearance of deeply stained granules in a slightly stained bacillus, or of darkly stained ends with a paler centre. The bacilli are very often in pairs, never in chains; they are semi-anaërobic, and thrive only at a somewhat high temperature, 20° to 42° C.

The Loeffler bacilli can be cultivated upon all the ordinary culture-media, but grow most vigorously on a mixture of blood serum and nutrient bouillon, as given by Loeffler. On this, solidified, the bacilli grow as large, round, elevated, grayish-white colonies, with the centre more opaque than the somewhat irregular periphery.

The Sections of Diphtheritic Membrane show on the surface and in the most superficial portions of the pseudo-membrane Loeffler bacilli mixed with more or less numerous other micro-organisms. In the middle and deeper portions the Loeffler bacilli, alone or associated with streptococci, are usually the only organisms present. In the deepest layer there are very few bacilli and in the mucous membrane, as a rule, none. Extremely rarely they are found in the blood and viscera. Some of those bacteria which are associated with the Klebs-Loeffler bacilli in diphtheria, especially the streptococci, may be found in the mucous membrane, lymphatic glands, and internal organs.



Loeffler Bacilli Highly Magnified.

Toxic Albumins.—The toxic albumins produced by the diphtheria bacilli have been especially investigated by Roux and Yersin,[1] and Fraenkel and Brieger.[2] This toxic substance is of a proteid nature, precipitated by alcohol, soluble in water. Nearly pure, it is a white, amorphous mass of light specific gravity, and keeps its properties for a long time unchanged. Its extraordinary poisonous nature is shown by Roux and Yersin, in that four tenths of a milligramme of the substance, when inoculated, was sufficient to kill eight guinea pigs. If this poison be inoculated into a guinea-pig, it produces all the changes, except the pseudo-membrane, that the pure culture of the bacilli does. The long continuance of the toxic power of the poison in the body and its slow absorption from the locally infected tissues account for the deaths which occur some time after the entire disappearance of the bacilli from the infected throats.

The toxalbumin of diphtheria is very little, if at all, absorbed by intact mucous membranes, and can be swallowed by susceptible animals in large amounts, without danger.

Lesions.—In animals inoculated with the bacilli or these toxalbumins we find at the seat of inoculation a grayish focus surrounded by an area of congestion. The subcutaneous tissues for an extensive area around are congested and more or less œdematous. The adjacent lymph glands are swollen and the serous cavities usually contain an excess of clear or turbid fluid. The microscopical changes in the internal organs of animals dying of experimental diphtheria have been studied by Babes,[3] Welch[4] and Flexnor, and others.

In the liver there are found numerous smaller and larger masses of necrotic cells. These areas are permeated by leucocytes. Congestion with hemorrhages into the capsule and tissue are present. In the kidneys fatty changes occur in the epithelium of the tubes and glomeruli and a hyaline alteration of the glomerular capillaries and of the smaller arteries. In the spleen and lymph-glands the necrosis of cells is also present. Both the cell-bodies and nuclei of living cells are altered. The lungs show areas of intense congestion with hemorrhages into their tissue. The heart is nearly always the seat of fatty degeneration. The fibres of the voluntary muscles show degenerative changes. The number of leucocytes is greatly increased in the blood.

Experimental Immunity.—The exceedingly interesting results obtained by Fraenkel, Behring,[1] Brieger,[2] and others[3] in producing immunity in animals, gives the hope at least of practical results in the future. They found that the blood or serum of animals rendered immune against diphtheria had the power of rendering other animals, when injected into their bodies, also immune. In animals already infected the injections had the power of destroying or neutralizing the poison secreted by the bacilli. It was also found that the offspring of immune animals possessed a considerable degree of immunity. Their success in treating animals has been so great that the endeavor to cure human diphtheria is soon to be made.

Duration of Life in the Klebs-Loeffler Bacilli.—The life of the bacillus varies greatly according to the conditions under which it is placed. An agar tube-culture in the laboratory is still alive after seven months' growth, and a bit of membrane no larger than a pin's head still gives cultures of both the bacilli and the streptococci four months after its removal from the throat. Some have found bits of membrane kept in cloth to be still alive after six months. Probably in dark, damp, dirty places life remains even longer, while, on the other hand, under unfavorable conditions the bacilli may live only a few days.

The Conditions Necessary for the Infection of Man with the contagium of diphtheria are of great practical importance. Whether this can be implanted on the normal mucous membrane in man is still a question. Undoubtedly a lesion favors it. When the Klebs-Loeffler bacilli are implanted on the normal mucous membranes of susceptible animals they do not grow. The researches of Barbier[4] throw interesting light on this subject He found that a streptococcus which was associated with the Loeffler bacillus in all cases where marked redness and swelling were present, when implanted on the normal mucous membrane of the vagina in guinea-pigs, produced an acute purulent discharge, with redness and swelling. If with these cocci, or even four weeks later, the Loeffler bacilli were brought into contact with the mucous membrane, a severe diphtheritic inflammation was started which often caused death. If these results can be applied to man, they add a new importance to the discovery that streptococci are frequently present in slightly inflamed throats, and to their frequent association in the pseudo-membranes with the Loeffler bacilli.

Pseudo Diphtheria Bacillus.—The relation of this bacillus to that of true diphtheria is of much practical importance. Abbott[5] has recently given such an exhaustive review of this subject that it will only be necessary here to give a brief summary. The term is now used to define a group of bacilli which closely resemble the Loeffler, but which are without pathogenic properties in guinea-pigs. By some writers the term is used to cover varieties that show quite marked cultural and morphological differences.

It has been established that bacilli with all the characteristics of the Klebs-Loeffler, except their virulence, are to be found exceptionally where pseudo-membranes are absent. These are never numerous, only a few scattered colonies being found on plates or tubes. In some localities they are found rather frequently, in others rarely, or not at all. Roux and Yersin[6] found also that among those obtained from cases of diphtheria there were gra-

dations in virulence from those whose inoculation caused death in guinea pigs in twenty-four hours to those which produced only local changes. They found that those taken from mild cases are, as a rule, the least virulent. Beck found in some cases of true diphtheria both virulent and non-virulent bacilli.

As the result of a large number of experiments, Roux and Yersin hold that the morphological and cultural differences between the diphtheria and the pseudo-diphtheria bacilli are inconstant, and, when present, are insufficient to establish that they belong to different species. In this country the pseudo-diphtheria bacilli have been infrequently found. Prudden, in a large number of cases in New York, did not find them once. Koplik has found them a few times, and Abbott in fifty-three cases in four. In these studies the pseudo-diphtheria bacilli were met with only once, as proved by animal experiments. This whole subject needs further study.

For bedside diagnosis all cases which give typical colonies of bacilli resembling the Klebs-Loeffler should be regarded as true diphtheria; both because of the length of time consumed in animal experiments and of the impossibility of being sure that because the colony from which the inoculating culture was made was not virulent all the colonies were the same. This merely compels a few doubtful cases of diphtheria to be still considered as such.

Pseudo-membranous Inflammations in which the Klebs-Loeffler Bacillus is Absent.—The presence of streptococci in the pseudo-membranes and in the blood of fatal cases of diphtheria has been known for many years. Loeffler,[1] in 1884, described a class of cases where loss of substance with a gray yellow or necrotic base was a characteristic feature in which the Klebs-Loeffler bacillus was absent, but a streptococcus very abundant. He concluded that in these cases the frequency of the presence of the streptococci either means that the poison of diphtheria has been at first present, and thus prepared the way for the streptococci, and then vanished before examination, or that the streptococci are the cause of this peculiar form of pseudo-membranous inflammation. He came to the conclusion that the first supposition was the true one, that the streptococci were secondary to the Klebs-Loeffler bacilli.

Colony Slightly Magnified.

Streptococcus Colony. Agar Plate.

This streptococcus he isolated in three cases from the tonsils and in two cases from the internal organs. Both the biological characters and the general effects upon inoculated animals seemed to indicate a close relationship with the streptococcus pyogenes and erysipelatus. The changes produced upon the mucous membrane by its inoculation did not resemble closely the characteristic local lesions of diphtheria. From that time until the present year it seemed to be the aim in Europe, especially in Germany, to seek out for examination only typical cases of epidemic infectious diphtheria. In these cases the Klebs-Loeffler bacilli were constantly found, and they came to be looked upon more and more as the only etiological cause of all extensive pseudo-membranous inflammations, at least when they were not complications of infectious diseases.

In 1889, Prudden[2] published the results of a very careful bacteriological investigation of twenty-four cases of fatal pseudo membranous inflammation of the tonsils, pharynx, and larynx, which were all considered clinically to be diphtheria. These cases were mostly young children in two asylums where they had been exposed to scarlet fever and measles, and in some of whom these diseases had existed as a complication. In not one of these were the Klebs-Loeffler bacilli found, but in all but two streptococci. These were present in most of the cases in enormous numbers, as shown by the cultures. In three cases in which the viscera were examined they were found to contain a moderate number of streptococci. In the ducts of the mucous glands and in the lymph-spaces of the submucosa, the streptococci were found in greater or smaller numbers, also rarely in the tracheal and bronchial glands. The staphylococcus pyogenes aureus and albus were present in varying numbers, but hardly more frequently than in many apparently normal throats.

In sixteen of the twenty four cases, broncho-pneumonia[1] was present, and cultures made from the fresh broncho-pneumonic areas in fifteen of these gave large numbers of streptococci. The streptococci obtained from all these cases presented the same morphological and biological characters. They appeared to be identical with the streptococcus pyogenes.

From his investigations Prudden concluded that in a certain class of cases pseudo-membranes were caused by streptococci. Kolisko and Paltauf, Wurz and Bourges,[2] Sevestre,[3] Tangl,[4] Baginsky,[5] and others have found streptococci but no Loeffler bacilli in the pseudo-membranous inflammations occurring early in scarlet fever. Baginsky,[5] in his recent studies, found that in one hundred and fifty-four cases clinically diagnosed as diphtheria, there were thirty-four in the pseudo-membranes of which no Loeffler bacilli were present. In two cases of membranous rhinitis he found the bacilli present. These ran the usual mild course.

Martin,[6] in Paris, has just published a clinical and bacteriological study of the croupous deposits of two hundred children suspected of diphtheria. He found in seventy-two no Klebs Loeffler bacilli; of these, twenty-nine were croup cases. The mortality of these was far less than in those having true diphtheria. Some of the children had been exposed to scarlet fever and measles. He is of the opinion that the certain clinical diagnosis of these cases is impossible. A few examples of infection with diphtheria in the wards are given. He regards the association of different bacteria with the Loeffler bacilli as greatly modifying the course of the disease. As he used only blood-serum tubes, he probably has often overlooked the almost invisible colonies of the streptococci. He also believes that from the form of the Klebs-Loeffler bacilli one can judge somewhat of their virulence.

Aim and Scope of these Investigations.—The object of these studies has been to determine by the bacteriological examination of a large number of cases whether, in fact, pseudo membranous inflammations can be divided into two distinct classes, and, if so, in what proportion of the cases the Klebs-Loeffler bacilli are present; also to go further and see if, by combining in all cases a very careful clinical examination with a bacteriological one, it would not be possible to find some constant differences between the local appearances and general symptoms of true diphtheria and those pertaining to other croupous inflammations.

The cases recorded in the following pages include all those having pseudo-membranous inflammations admitted to the wards of the Willard Parker Hospital during four consecutive months; also a number sent to me by sev-

eral physicians, and six cases of membranous rhinitis from the throat classes of the Vanderbilt Clinic and the Roosevelt Hospital.

In all, one hundred and fifty-nine were examined; these will be studied in the following classes: True diphtheria, those in which the Klebs-Loeffler bacilli are present alone or with other bacteria; pseudo-diphtheria, those in which the Klebs-Loeffler bacilli were never present, but some form of cocci, usually streptococci.

For comparison, the following were also examined bacteriologically: Follicular tonsillitis, 10; peritonsillar abscess, 5; acute pharyngitis, 5; chronic pharyngitis, 5; hyperæmic throats in scarlet fever, 10.

Technical Observations.—To obtain the material for examination two methods were employed. Where a piece of membrane could be removed without injuring the throat, this was done by means of a long, slender pair of forceps, carefully sterilized. For the cases in which this was impossible, a number of cotton plugs [1] had been prepared by wrapping small portions of absorbent cotton around the ends of slender sticks, one inch in length, which were then placed in a tube and sterilized by dry heat. Taking one of these in the forceps, it was rubbed gently, but rather firmly, against any visible pseudo-membrane; when none was present, the cotton was rubbed against the tonsils and pharynx. The bit of membrane or cotton plug was then gently drawn three or four times across the surface of a six per cent. glycerine-agar Petri plate, making equally distant lines of inoculation. Taken to the laboratory, here the bit of membrane or swab was drawn across a blood-serum tube and then rubbed in a few drops of sterilized water. With a sterilized platinum loop a drop of this turbid fluid was taken up and drawn across two or more solidified Loeffler's blood-serum tubes, and a second drop across a second agar plate. The tubes and plates were placed in the thermostat and kept at 37° C. for twenty-four hours. From the membrane, or swab, two cover-glass smears were prepared, stained with Loeffler's methyl blue solution, studied under the microscope, and the forms of bacteria seen recorded. On the following day the colonies of the Loeffler bacilli, when present, in every case had reached a size sufficient to be distinctly seen on both the blood-serum tubes and agar plates, and, under the microscope, showed their extremely characteristic appearance on the latter.

It is necessary to be extremely careful to have the glycerine-agar faintly alkaline, to have proper peptone, and to use only fresh, moist plates, otherwise there may result an entire failure to get any growth of the Loeffler bacilli.

In these investigations the special object in view was to discover in the cultures the presence, or absence, as well as the relative abundance of the Klebs-Loeffler bacilli, the streptococci, and the staphylococci. Any other forms of bacteria that appeared frequently or in large numbers were also investigated.

The Comparative Value as Culture-media of Blood-serum and Six-per-cent. Glycerine-Agar.—On the solidified blood-serum mixture suggested by Loeffler the Klebs-Loeffler bacilli grow more rapidly and surely than on any other of the usual solid media. The growth of the colonies, though fairly uniform, is not sufficiently characteristic to certainly identify them, for certain frequently present cocci grow with almost the same rapidity and appearance. The usefulness of the serum is limited to tubes, from its slight cloudiness and the great difficulty of making plates.

On glycerine-agar the growth of the bacilli is less rapid, but still vigorous when made from fresh bits of membrane or swabs. The gross appearance of the colonies is here also very similar to those of several forms of cocci. The appearance of the colonies under the microscope is, on the other hand, extremely characteristic and entirely different from those of any other bacteria occurring in the throat, with the possible exception of the pseudo-diphtheria bacilli. Glycerine-agar in tubes is much less useful than the serum, but in plates it has many great advantages, and if it were not that under certain conditions, when still capable of growing on the blood-serum, the Loeffler bacilli are unable to grow on the agar, the agar plates could entirely replace the serum tubes. This absence of growth on agar has occurred in two cases where frequent irrigation with 1 to 4,000 bichloride of mercury had been employed, also from two long-dried swabs.

In disinfection work, cultures would be obtained on blood serum when they no longer appeared on the agar. With these exceptions the plates always contained colonies of the Loeffler bacilli whenever the tubes contained them.

Throat cultures show the most characteristic growth under the microscope when the plates are examined after remaining from sixteen to twenty-four hours in the thermostat. The colonies of the different bacteria common to the throat have then attained a characteristic growth and are still for the most part distinctly separate. At this time, after some familiarity with the work, you can rapidly run over the plates, placed under the microscope, with a low power lens, and acquire a knowledge not only of how many varieties of organisms are present but also the relative proportion. The colonies can then be further studied by a higher power lens and under the microscope accurately fished.

For the photographs of six of the plate cultures, shown in the accompanying Plate, I have to thank my friend Dr. Edward Leaming. These give the usual appearance of the plates made from fresh membranes or swabs. At times the colonies are much closer together, at other times less so than in these. They show at a glance the actual and relative size of the colonies, and to some extent their appearance after twenty to thirty hours' growth at 37° C. It can be readily seen how thoroughly the isolated colonies can be investigated when the uncovered plate is put on the microscope-stand and each colony individually studied with any power lens desired.

Glycerine-agar plates in which the media has been tested are sufficient when the cultures are to be made immediately from throats in which frequent antiseptic irrigation has not been used. Whenever the bacilli may have been injured from antiseptics, drying, or any other cause, the blood-serum tubes should also be used to insure the growth of the Loeffler bacilli.

For the simple determination of the presence or absence of the Loeffler bacilli the blood-serum suffices. I believe that the failure to fully recognize that there are many extensive pseudo-membranes, neither due to the Loeffler bacillus nor occurring after scarlatina, is owing to the almost exclusive use of blood serum tubes, since in tubes it is impossible to satisfactorily use the microscope to identify the smaller colonies, and before they become visible to the eye they are often overgrown by the more rapidly growing bacteria.

When the colonies of the bacteria sought for were plainly isolated, tube cultures were immediately made from a characteristic colony; when not, a sowing was made on a fresh plate and isolated colonies obtained.

Animal Inoculations.—From the first or second generation of the Klebs-Loeffler bacilli, tubes of faintly alkaline nutrient bouillon were inoculated. The tubes were removed from the thermostat on the fourth day. Two-thirds of the clear bouillon was poured off and the remainder well shaken. One-third cubic centimetre of this fluid, turbid with the bacilli, was inoculated into the sub-

[1] In a number of trials, in which, from the same cases, plates were made both from bits of membrane and from the swabs, the latter proved as trustworthy as the former. For the use of physicians, who supplied me with cases from outside the hospital, I kept a number of strong glass tubes, two and one-half inches in length by one-half inch in thickness. Each tube contained an absorbent cotton swab, and was plugged with cotton. The tubes and their contents were then placed in the hot-air sterilizer. These could be carried in the pocket. After use at the bedside they were returned to the laboratory, where the plates and tubes were made.

cutaneous tissue of the side of the abdomen of a guinea-pig. Guinea-pigs were inoculated from cultures of twenty-two of the cases in which the Klebs-Loeffler bacilli were present. In nineteen death followed with typical pathological changes. In no case were the bacilli, or any other bacteria, obtained in the cultures made from the heart's blood, the liver, or spleen. In no case were any other pathogenic bacteria than the Klebs-Loeffler bacilli obtained from the cultures made from the œdematous fluid and congested tissue in the immediate neighborhood of the point of inoculation.

The temperature in the animals fell after inoculation in every case but one, in which a temporary rise occurred, and remained from one to three degrees below the normal until death.

The streptococci taken from four cases of true diphtheria and from four cases of pseudo-membranes in which the Loeffler bacilli were absent were inoculated in rabbits. The temperature of the rabbits rose after inoculation, in every case, from one to five degrees. In two local abscess and sloughing of tissue occurred. In three temporary swelling and redness and in three no reaction appeared. Four died between the fourth and fifth weeks. No streptococci were obtained from either the blood or viscera of the fatal cases.

Description of the Willard Parker Hospital.—This hospital is under the control of the New York City Board of Health and to it are sent diphtheria and scarlet-fever cases. The diphtheria wards, in which the majority of the cases here studied were treated, comprise three large, high rooms, connected by a hallway. Two are used for the women and children, and one for the men. As far as possible, the convalescent and doubtful cases are separated from those having true diphtheria; but owing to the frequently crowded condition of the wards, this often cannot be done. The floors are of hard wood, and are washed daily with 1 to 1,000 bichloride solution. The iron bedsteads are carbolized each morning. Where patients soil their beds, the sheets and spreads are changed daily; in other cases, weekly. All patients have their nostrils and throats syringed with a 1 to 4,000 bichloride solution, the bad cases every half hour, the convalescents three times a day. No swabbing of throats is allowed. All clothes brought to the hospital are disinfected, and are only returned when patients leave. Patients are also required to take a bath when they go (also, if possible, when they come), washing the hair with a 1 to 1,000 bichloride of mercury solution.

Cases of laryngeal dyspnœa when urgent, or when not relieved by vomiting and calomel fumigations, are intubated. The only routine constitutional treatment is to give alcoholic stimulants throughout the course of the disease to those showing any tendency to heart failure. Tube cases are fed lying on the lap with lowered head. These details are necessary to show the conditions under which the patients were placed, and to avoid a repetition of the account of the treatment in the clinical histories which follow. The wards for scarlet fever are on a different floor, and have the same arrangement of rooms.

Methods of Clinical Study.—I made daily rounds with Dr. Lester, the resident physician; each case was carefully observed, the appearance of the throat, and the complicating conditions of the larynx and nostrils were noted. As far as possible sketches were made, and the changes occurring from day to day noticed. The figures for pulse, temperature, and respiration were taken from the hospital charts—the temperature in children being always taken by the rectum, in adults by axilla. The urine analyses were also obtained from the hospital records. Cultures were made from every case on the day of admission, those which showed very numerous colonies of the Loeffler bacilli were not examined again for three days, and then every other day till the bacilli had twice proved absent. Cultures were made twice from cases of croupous tonsillitis. Those having croupous laryngitis were examined daily, until all doubt as to the presence or absence of the Loeffler bacilli was dispelled, swabs and bits of coughed-up membrane being used. The same care was taken in extensive pseudo-membranous inflammations, in which the Loeffler bacilli were absent. During the last six weeks some of the cases were subjected to only one thorough bacteriological examination.

True Diphtheria (Clinical histories and bacterial examinations of 27 illustrative cases from the 54 in which the Klebs-Loeffler bacilli were present).—The aim is to present in the histories only the most important points.

Case I. February 6th.—Molly F——, aged five; membranous laryngitis; intubation; death. Clinical history: Well nourished; admitted with marked laryngeal dyspnœa; slight adherent patches on tonsils; no pain on opening mouth; no swelling of glands of neck. Temperature, 101° F.; pulse, 118; respiration, 34. Vomiting and fumigations not relieving the dyspnœa, she was intubated.

February 9th.—Temperature has remained between 100 and 101° F.; pulse and respiration remain about the same. Patient is very languid, and has at times dyspnœa, which is relieved by calomel fumigations. Patches still remain on tonsils.

February 12th.—Tonsils clean. Condition unchanged.

February 18th.—Temperature normal. Tube removed.

March 2d.—Patient taken home; she is weak, can hardly stand, and cannot speak above a whisper. Since the tenth day considerable quantities of albumin have been present in the urine. Considerable emaciation.

March 11th.—Patient returned for laryngeal dyspnœa, apparently due to laryngeal paresis. She was intubated.

March 24th.—Tube removed. Patient is anæmic; muscles are somewhat atrophied; some albumin persists in urine. Remains in bed.

March 28th.—Is sitting up and gaining slightly in strength. Returned home. Died two weeks later at home, apparently from nephritis.

Bacterial examination: Cover-glass smear showed many fairly typical Loeffler bacilli. Plates and tubes showed almost a pure culture of vigorous growing colonies of the Klebs-Loeffler bacilli. A colony was replated, and from this new growth a bouillon tube was inoculated. A guinea-pig inoculated with ½ c.c. of bouillon culture died in forty-three hours with characteristic lesions. A pure culture of the Loeffler bacilli was obtained from the tissue at seat of inoculation, while the plates from the heart and organs were sterile.

Case II. February 29th.—Harry S— , aged two; intubation; membranous laryngitis; recovery. Clinical history: Admitted with marked laryngeal dyspnœa. Intubation gave complete relief. No membrane visible anywhere in throat. Very slight prostration. Temperature, 101° F.; pulse, 124; respiration, 32. On sixth day tube was coughed up. Except for the slight prostration there were no bad symptoms.

Bacterial examination: Plates and tubes made from a swab of the throat contained a number of typical colonies of the Klebs-Loeffler bacilli. Cultures made on following days gave none. Streptococci were always present. Guinea-pig died in forty-eight hours with characteristic lesions.

Case III. February 20th.—Sarah S——, aged four; intubation; death. Clinical history: The child had been intubated before admission; heart irregular and weak; a few grayish semi-adherent patches on tonsils. Temperature, 100.6° F.; pulse, 134; respiration, 42.

February 22d.—Breathing badly, swallows with difficulty. Died, 7.15 P.M.

Bacterial examination: Plates show many typical colonies of Loeffler bacilli, and many of streptococci.

Case IV. February 23d.—Benjamin J——, aged two

years and ten months; intubation; death; extensive membrane. Clinical history: Thick, greenish-gray, adherent pseudo-membrane on uvula, anterior faucial pillar and pharynx; croupy; glands of neck swollen. Temperature, 101° F.; pulse, 126; respiration, 38. Very restless.

February 26th.—Intubated, with relief of laryngeal dyspnœa.

February 27th.—Heart failure and death.

Bacterial examination: Plates revealed a great number of active growing colonies of the Loeffler bacilli, and some of streptococci. Guinea-pig inoculated died between forty-eight and sixty hours with characteristic changes.

Case V.—Private case, aged one; intubation; death; extensive membrane. Clinical history: Soft, grayish, pseudo-membranous patches on tonsils, base of uvula, and in nostrils. Temperature, 101° F.; pulse, 120. Membrane spread slowly over pharynx, and on fifth day invaded the larynx; dyspnœa gradually increased; tissues of neck became greatly swollen; intubated with but slight relief. Died on seventh day. Temperature never above 102° F.

Bacterial examination: Many colonies of the Loeffler bacilli and of streptococci.

History of infection: Three days before first symptoms child had been put in a crib for a few hours, occupied, two weeks before, by a child who had passed through a dangerous attack of diphtheria.

Case VI. February 28th.—Rachel M——, aged five. Death after disappearance of the membrane. Clinical history: Both tonsils, anterior pillars, left side of uvula, and soft palate covered by a thick, firmly adhesive, grayish pseudo membrane. Dirty discharge from nose. Temperature, 99° F.; pulse, 110; respiration, 24. Apathetic.

March 1st.—Croupy, relieved by calomel fumigation. Temperature, 99.5° F.

March 7th.—Thick membrane has separated. Superficial ulceration on faucial pillars and tonsils covered by thick purulent discharge. Since the third the urine has contained large amounts of albumin. Is very weak and apathetic Speaks in whispers and swallows with difficulty.

March 15th.—Copious discharge continued, and patient seems unable to swallow or spit it up. Patient suddenly began to breathe with feeble gasps and died at 7.30 A.M.

Bacterial examination: Cover-glass from smear gave an almost pure culture of typical Loeffler bacilli. Cultures gave a large number of colonies of the Loeffler bacilli, and a smaller number of colonies of micrococci which appeared as diplococci and in rows of two to eight. After the disappearance of the membrane no more Loeffler bacilli were present, the micrococci above noticed and many other forms replacing them.

Guinea-pig died in forty-eight hours with characteristic lesions.

Cases 7 to 10 in one family. Malignant diphtheria.

Case VII. March 6th.—Cora B——, aged twenty-six, the mother; died. Clinical history: Has been sick five days. Uvula, posterior fauces, tonsils and pharynx greatly swollen and covered by a very thick, yellow-gray membrane, nostrils occluded by membrane. Lymph-glands hard, slightly swollen. Temperature 100.8° F.; pulse, 106 and feeble; respiration, 26. Is apathetic, can hardly swallow or whisper. Feels that she is choking.

March 8th.—No improvement. Nasal passages obstructed by thick membrane; sweetish, offensive odor. Can hardly swallow or spit up the copious discharge. Patient grew worse on the 10th. Pulse became imperceptible and death occurred at 4 P.M.

Case VIII. March 6th—Maud B——, aged five, daughter of last; death after disappearance of membrane. Clinical history: Sick for three days. At base of uvula and on tonsils are large patches of thick, yellowish-gray pseudo-membrane. Nasal passages occluded by thick, fibrinous membrane. Same odor as from mother. Slightly croupy. Patient seemed at first to do well. The membrane gradually separated, and on the 11th the throat was clear of membrane. Some ulceration on fauces. On the 14th began to vomit food. This continued on 15th. Heart became weak and patient died at 10 P.M.

Case IX.—Clifford B——, aged one, son of Cora B——; died. Clinical history: Sick three days. Pharynx, tonsils, and cavities of nose lined by a thick, offensive, adherent pseudo-membrane. Croupy. Patient is cyanotic and septic, and very restless. Died at 1.10 P. M.

Case X.—George B——, aged thirty; father. Clinical history: Has had for one day sore throat, pains in limbs, and prostration. Whole right tonsil is covered by a thick, soft, grayish smear, which can easily be removed, leaving adherent follicular deposits. Slight adherent patch on right anterior faucial pillar.

March 8th.—Merely follicular deposits on tonsil and slight membrane on anterior pillar.

March 14th.—Throat clean, except small patch on right anterior pillar.

March 17th.—Throat clean. Feels well.

Bacterial examination: All four cases gave such typical smears on cover-glasses of the Loeffler bacilli that an almost certain bacteriological diagnosis could be immediately made of true diphtheria. Besides the Loeffler bacilli, all had many colonies of a streptococcus which grew rapidly without forming looped colonies. In hanging drop it grew in short chains and as diplococci. The plates showed colonies of numerous other varieties of cocci and bacilli.

Guinea pigs were inoculated from cultures of eight and ten. The animals died in seventy-two and twenty-four hours with characteristic changes.

The history of the spread of the contagion in these cases is interesting. Two months before, a child living on the floor below them had what the doctor called diphtheria. Until a few days before the sickness of Cora B——, the two families had kept apart. For the last few days they had visited each other, and Cora had carried and played with the child who had recovered from the diphtheria. When the mother took sick she was still allowed to nurse and carry the children. Three days later, the children were discovered to have contracted the disease. The mother, too sick longer to nurse the children, confided their care to the father, who himself became infected. Antiseptic cleansing of the nostrils and throat was neither used in treatment nor prophylaxis in these cases, before their admission to the hospital.

Case XI. February 23d.—Charles B——, aged thirty; recovery. Clinical history: Both tonsils, faucial pillars, and base of uvula are covered by a firmly adherent, thick pseudo-membrane of grayish color. Diffuse infiltration of adjacent tissues of neck.

February 24th.—Membrane has extended forward over palate.

February 27th.—Membrane separating in large pieces.

February 29th.—Clean, except for superficial ulceration of mucous membrane of soft palate.

On first two days temperature was about 101° F., after that below 100° F. On the tenth day albumin appeared in the urine.

Bacterial examination: Cultures made from bits of membrane showed many colonies of the Loeffler bacilli, until the 29th, when they ceased to appear. There were always many colonies of the streptococcus present.

Case XII. February 25th.—Gustav V——, aged twenty-one. Recovery. Clinical history: Thick adherent patches of pseudo-membrane on tonsils and lateral walls of pharynx. Membrane began to peel off on the 27th, and had all disappeared on the 29th. After the first day the temperature was normal. Most abundant colonies are of the Loeffler bacilli; some colonies of streptococci present. After the 29th no more Loeffler bacilli present.

Guinea-pig inoculated died in seventy hours, with usual conditions.

Case XIII. February 16th.—Mary C——, aged twenty; malignant; death. Clinical history: Has been sick two days before admission. Tissues of pharynx and palate swollen and œdematous. Whole of uvula, tonsils, part of soft palate, and part of pharynx covered by a thick, adherent, dirty gray pseudo-membrane. Much swelling of tissues of neck. The breath has a foul, sweetish odor. Patient is much depressed. Temperature, 98° F.; pulse, 100; respiration, 28. The pharynx, tonsils, and soft palate became one swollen mass covered by sloughing membrane. Swallowing difficult. For the last two nights patient was delirious and restless.

February 20th.—Pulse became rapidly weaker, and death occurred. Bacterial examination: Plates showed many varieties of bacteria, of which the Loeffler colonies comprised about one-third. Streptococci, micrococci, and bacilli were present.

Case XIV. March 24th.—Polly K——, aged thirty; malignant; recovered. Clinical history: Sick two days. Pharynx, tonsils, and soft palate swollen and œdematous. Tonsils, faucial pillars, and part of soft palate covered by a rotten, grayish-green, adherent pseudo-membrane. Great prostration. Temperature, 101.4° F.; pulse, 100; respiration, 20.

March 25th.—Condition unchanged. Temperature, 99.4° F.

March 29th.—Membrane nearly disappeared. Condition improved. Three children of this patient died. Bacterial examination: Many colonies of the Loeffler bacilli, many of the streptococci and others.

Case XV.—Child, aged six weeks; death; private practice. Clinical history: On first day small adherent patch on left tonsil and on base of uvula, also a piece of membrane hanging down from naso-pharynx, membrane spread over pharynx, and on third day into larynx. Child died on the fifth day. Glands were never swollen, and temperature did not rise above 99° F. until a few hours before death. The day before the illness of the child was noticed the mother was discovered to have diphtheria, and the child immediately removed, but too late. The mother went through a severe illness, also without fever, but recovered. Bacterial examination: An almost pure culture of Loeffler colonies on plates. No streptococci.

Animal inoculation: Guinea-pig died in fifty hours, with fairly characteristic lesions.

Case XVI.—Child, aged two; recovery. Clinical history: Adherent gray patches, first on tonsils, then on pharynx and roof of soft palate. On seventh day spread to larynx and caused great dyspnœa. Calomel fumigations given every hour. Child never seemed very ill, except for the dyspnœa. Temperature never above 100° F. Glands not swollen.

Bacterial examination: The majority of the colonies were those of the Loeffler bacilli. Numerous colonies of micrococci were also present. No streptococci found.

Case XVII. February 13th.—Child, aged six; private practice; recovered. Clinical history: When first seen tonsils were swollen. Next day adherent patches seen on tonsils. Tonsils became clean five days later. Some days afterward child was noticed to limp, and slight paresis of muscles of left side was found. In the next house, the week before, there was a case of clinical diphtheria, and this child played with the children from the other house.

Bacterial examination: Many colonies of Loefiler bacilli and many scattering forms.

Case XVIII. April 25th.—Minnie M——, aged twelve. Abscess tonsil; diphtheria. Comes from an asylum from which three others with diphtheria have been received. Has complained of sore throat for two days. Both tonsils and left peritonsillar region swollen and hyperæmic. Adherent patches on left tonsil, follicular deposits on right. Temperature, 102° F.; pulse, 90; respiration, 24. Abscess in left tonsil ruptured and discharged a large amount of pus at the moment of examination. Recovered entirely by fourth day. Cultures gave numerous colonies of the Klebs Loeffler bacilli and of long-chained streptococci.

Guinea-pig inoculated died in forty-four hours, with characteristic lesions. Plates and tubes from tissue at point of inoculation gave abundant colonies.

Case XIX. February, 1892.—Child, aged six weeks; private practice; death. Clinical history: Began with bloody discharge and membrane in nose. Membrane spread to pharynx, tonsils, and larynx. Death about the tenth day. Father of child had been attending diphtheria cases.

Bacterial examination: Cultures from a piece of membrane gave abundant colonies of the Loeffler bacilli and of the long-chained streptococcus. A piece of membrane taken three days later from the nose gave very numerous colonies of the staphylococcus pyogenes aureus. Guinea-pig died in forty-eight hours, with characteristic lesions, after inoculation with the bacilli.

Case XX. February 13th.—Henry K——, aged sixteen. Clinical history: For one week a room-mate had been sick with diphtheria, swabs from whose throat gave an almost pure culture of the Klebs Loeffler bacilli. On first day of his illness both tonsils and adjacent borders of pillars were covered by a thick, soft, dirty pseudo-membrane. The pharynx and fauces were swollen and deeply injected. Temperature, 103 F.; pulse, 120. Glands swollen.

February 14th.—The tonsils still swollen and painful, but the diffuse membrane disappeared, leaving only croupous patches confined to the tonsils.

February 17th.—Small follicular deposits still remain.

February 18th.—Tonsils clean, though still swollen.

There was never any albumin in urine. Temperature and pulse sank to normal on the second day.

Bacterial examination: Very numerous colonies of the Loeffler bacilli, some streptococci.

Case XXI. March 23d.—Cornelius V——, aged seven. Clinical history: Tonsils, anterior faucial pillars, and roof of soft palate covered by a thick, grayish-white, adherent membrane. Temperature, 101° F.; pulse, 120. Marked swelling in adjacent tissues of neck. Considerable prostration.

March 27th.—Membrane peeling off. Glands of neck less swollen. Temperature, 100° F.; pulse, 130. Prostration still marked.

March 29th.—Expelled a large piece of membrane from nose.

April 1st.—Throat clear. Temperature, 98.6° F.; pulse, 130. Made a slow recovery.

Bacterial examination: Very abundant colonies of Loeffler bacilli and many streptococci.

Case XXII. March 23d.—John V——, aged five, brother of previous case. Clinical history: Slight adherent patch on left tonsils. Hardly complains at all. Temperature, 100° F.

March 25th.—Patch smaller.

March 27th.—Throat clean. Feels well.

Bacterial examination: Cover-glasses show many typical Loeffler bacilli, of chain cocci and diplococci. The cultures from both cases contained many colonies of the Loeffler bacilli, streptococci, and micrococci.

The previous week the oldest sister had croupous inflammation of the tonsils and soft palate. The children were not isolated. The second child had absolutely no symptoms. Treatment with spray and douche of 1 to 4,000 bichloride solution was begun probably a few hours after infection.

Case XXIII. February 17th.—Gussie G——, aged three and a half; diphtheritic rhinitis; recovery. Clinical history: Slight deposits on left tonsil. Obstruction to nasal breathing and dirty discharge from the nose.

February 21st.—Small adherent patches still on tonsils. Glands on left side of neck swollen and painful.

February 23d.—To day a large, thick, fibrinous pseudo-membrane, four inches in length, was washed from the

nose. It was a partial cast of both nostrils. Patient doing well. Tonsils almost clean.

On the 25th scarlet fever developed, from which she finally recovered. Temperature never rose over 101° F. until the development of the scarlet fever.

Bacterial examination: From the pharynx the culture showed many typical colonies of the Klebs-Loeffler bacilli. From the membrane from the nose only a very few colonies were obtained, among which were a few of the Krebs-Loeffler bacilli and a few of the streptococci.

Membranous Rhinitis.—Case I.—January 19, 1892. Roosevelt Dispensary. Service Dr. Jonathan Wright. Aged three. Recovery. Clinical history: Right nostril occluded by a thick succulent membrane. Left shows in front small adherent deposits. Upper lip eczematous with a few pustules. Bloody secretion from nose. Pharynx and larynx free. Temperature by rectum, 100° F.; pulse, rapid. Removal of a piece of membrane caused considerable bleeding. Patient never seemed really ill. On the fifth day the nostrils were free from membrane. Still considerable discharge and swelling. No albumin in urine.

Bacterial examination: Cover glass preparations from membrane showed cocci, diplococci, and bacilli, among which were some fairly typical Loeffler bacilli. Cultures contained numerous colonies of Loeffler bacilli and of the long-chained streptococci and of a few other micrococci.

Guinea-pig inoculated with 1 to 2 c.c. of bouillon culture, second generation, of the Loeffler bacilli, died on the fifth day, with characteristic lesions. A rabbit was inoculated in the ear with 1 to 2 c.c. of a bouillon culture, two days old, of the streptococci. On the second day rabbit's temperature was 102° F.; the ear about inoculation somewhat reddened. On third day temperature 103° F., considerable redness and œdema of the whole central half of ear was present. The temperature and local signs of inflammation then subsided.

Case II.—Gertrude B——, aged four. Discharge and occluded nostrils for six days; peevish; anæmic. Both nostrils filled in front by a thick, succulent, adherent, light-gray membrane. Free hemorrhage on removal. Pharynx clear of deposit. Temperature, pulse, and respiration nearly normal. Urine, 1.007, clear, no albumin or casts. On sixth day membrane separated.

Case III.—Tom Mc——, aged four and a half. Vanderbilt Clinic, service Dr Simpson. Discharge and occluded nostrils one week. Both nostrils filled by thin, grayish-white, adherent pseudo-membrane. Temperature, 100° F.; pulse, 130. Urine, 1.010, clear; no albumin or casts. Nostrils clear sixth day.

Case IV.—Ellen B——, aged eighteen months. Roosevelt Dispensary. For six weeks has had an otitis media. For one week discharge from nose. On septum and turbinated bones thin, grayish-white, adherent membrane. Child seems well. Membrane all disappeared on fifth day.

Case V.—E. W——, aged five. Same history as previous cases. Membrane separated sixth day. Never appeared sick.

Case VI.—Mary B——, aged three. Membrane separated sixth day. Never appeared seriously ill.

In all the latter five cases of membranous rhinitis quite numerous colonies of the Klebs-Loeffler bacilli were present, in three associated with streptococci, and in two with staphylococci. From the first four, guinea-pigs were inoculated. One died on the fifth day and one on the seventh. The other two appeared sick for a few days and then recovered. In the neighborhood of the inoculation some induration could be felt. The slight virulence of the bacilli is remarkable.

These cases are very interesting. Like those observed by all other observers they ran a benign course. The only precaution to prevent the spreading of the contagion was antiseptic irrigation. No history of infection was obtained in any. In all six cases the colonies of the Loeffler bacilli grew rather feebly, both on the blood-serum and on the agar. The bacilli from the agar were small and often pointed, from the blood-serum and broth long and slender, with swollen ends. The cultures died out more quickly than those from ordinary cases. The bacilli in the membrane were rather long and slender, with few clubbed forms.

Cases of Laryngeal Diphtheria Requiring Intubation.

Number.	Name.	Age.	Lesion.	Temperature, pulse, and respiration on admission.		Result.
1	Lizzie D...	16 mos.	Croupous laryngitis.	Temp., 102; pulse, 130; resp., 40.	Intubated 3d day; died 4th day.	Died.
2	Maggie D..	4 yrs.	Croupous laryngitis; slight patches tonsils.	Temperature, 101.6; pulse, 118; resp., 28.	Intubated before admission.	Died.
3	Margt. G..	1 yr.	Croupous laryngitis; tonsils and uvula.	Temp., 101; pulse, 150; resp., 56.	Intubated 4th day; died 6th day.	Died.
4	Lena G....	4½ yrs.	Croupous laryngitis; slight patches tonsils.	Temp., 102; pulse, 140; resp., 42.	Intubated 4th day; died 6th day	Died.
5	Abram A...	2½ yrs.	Croupous laryngitis; tonsils. Pneumonia?	Temp., 104; pulse, 136; resp., 46.	Intubated before admission; died next day.	Died.
6	Ike S.....	18 mos.	Croupous laryngitis; bronchitis.	Temp., 100; pulse, 132; resp., 30.	Intubated on admission.	Recovered.
7	Cbarles H..	.....	Croupous laryngitis; scarlet fever.	Temp., 103.	Intubated on admission.	Recovered.
8	Female	4 yrs.	Croupous laryngitis; measles.	.....	Intubated	Recovered.
9	Female	5 yrs.	Croupous laryngitis; tonsils and pharynx.	.....	Intubated	Died.
10	.....	5 yrs.	Croupous laryngitis; slight patches tonsils.	.....	Intubated	Died.
11	.....	2 yrs.	Croupous laryngitis.	Reported in histories of Cases No. 1–5.	Intubated	Recovered.
12	.....	4 yrs.	Croupous laryngitis.		Intubated	Died.
13	.....	2½ yrs.	Croupous laryngitis; pharynx and tonsils.		Intubated	Died.
14	.....	1 yr.	Croupous laryngitis; pharynx and nostrils.	.....	Intubated	Died.

Whole number of cases requiring intubation, 14, of which 10 died and 4 recovered. Ages varied between one and five years. In Case 8 the bacilli grew and appeared like those in the membranous rhinitis cases. In 6 of these no membrane was visible anywhere above the larynx. In 1 scarlet fever, and in 1 measles existed as a complication.

Table of Diphtheria Cases not Included in the List of Cases of Membranous Rhinitis and Laryngitis.

Résumé of Points of Interest in the Fifty-four Cases of True Diphtheria. (The reliability of cultures and of the immediate diagnosis from cover glass smears.)—In every case in which cultures revealed the Loeffler bacilli during any part of the disease the first examination disclosed numerous colonies. This would seem to show that cultures made from a fresh swab, or bit of membrane, can be thoroughly relied upon to show the presence or absence of the Loeffler bacilli as soon as the pseudo-membrane is developed. After the complete separation of the membrane they were in every case missed. In many cases an examination of cover-glass smears, when made from fresh swabs or membrane, gives an immediate reliable diagnosis. This requires great care and should always be controlled by cultures. Swabs from the pharynx of cases, in which no membrane was visible, also give knowledge of the bacteria infecting the larynx.

Methods of Spreading the Contagion.—Cultures made from the dried stains on spreads, pillow-cases, and sheets, where soiled by the expectoration of diphtheria patients, showed, in every case, at least a few colonies of the Loeffler bacilli. (See Photograph 4.)

We know by actual experiment that, under favorable conditions, when mixed with shreds of tissue and mucus, they live for many weeks. The sputum of patients, though apparently not containing any bits of membrane, is yet usually crowded with them.

More than one-third of the cases gave a clear history of having been brought in contact with the persons or clothes of those suffering from, or having recently had, severe pseudo membranous inflammations, diagnosed as diphtheria; and in eight the diagnosis had been verified by finding the Loeffler bacilli.

Case V. brings out strongly the manner in which diphtheria breaks out in unexpected places. The child, aged five, is taken out of town and left to sleep in an infected bed for a few hours, and dies ten days later. In another, a child is sent away for safety, but carries with him his infected clothes, and some of his playmates take the disease and die, while he himself escapes.

In another, five weeks before there existed diphtheria in the flat below. The first new patient taken sick was a child, aged two and a half years, three days later another, aged four, and then the mother herself. The children died, the mother went to the hospital and finally recovered. When she left home, her seven months' baby went to a friend's, where, three days later, two of the children developed diphtheria, and then finally the baby itself. The baby came to the hospital and died, one of the other children died.

Cases VII. to X. show the methods of transmitting the disease from one to the other. The sick mother carries the children and infects them. The father cares for them and is himself infected.

Physicians certainly are not careful enough to avoid carrying infection in their clothing, and to make sure that those whom they send from an infected house do not take it with them. In several of those in which the history of infection was investigated, great carelessness on the physician's part, in regard to warning those about the sick, was shown. The large number of cases of diphtheria which occur in the families of physicians should lead them to realize the danger of their carrying infection to others.

The practice, in hospitals for contagious diseases, of wearing gowns when examining patients, should be partially adopted by practitioners. The frequent crowded condition of the diphtheria wards in the hospital forces the placing in the same room, and often in adjacent beds, those having true diphtheria and those not having it.

At first it would seem that the contagion must be carried from one to the other, but, as far as the Resident Physician knows, this has not taken place in the last two years, and it certainly never occurred during these investigations.

The great attention paid to cleanliness in the wards and the sterilization of instruments of examination account partly for this, but the routine cleansing of the nostrils and throats of all patients with a weak bichloride of mercury solution has also an important share in giving this freedom from infection. The important fact is that it seems possible to almost entirely prevent the spread of diphtheria if proper precautions are taken.

Age.—Of the 54 cases, 43 were under 10 years; 2 were under 8 weeks; 11 were adults.

Mortality.—Twenty-five died out of the 54; 4 deaths occurred in the 11 adults; 10 of the 14 cases requiring intubation died.

Effect of Treatment.—The patients that died in the hospital were, without exception, those that on admission had either very extensive membrane or laryngeal complications. In only three was there any extension of the disease after irrigation with 1 to 4,000 bichloride solution had been commenced. In a number of families where different members had had the disease for different lengths of time, those longest sick without treatment did badly, while those just attacked did very well. In these cases the virulence of the bacilli and the family predisposition were the same in both the early and later cases, so that the great difference in the course of the disease in the two classes was probably the effects of the treatment.

Location of Pseudo-membrane.—Of the 54 cases, in 6 the disease was confined to the nostrils, in 5 to the larynx and bronchi. In all others the tonsils were more or less involved. In bad cases the soft palate and uvula were extensively invaded. In the adults, the pseudo-membrane was generally thick, usually extensive, and of a dirty grayish color. In bad cases, the membrane became very thick and offensive. In some of the children the membrane presented the same appearance as in adults, while in others it was thin and grayish white, often simply in the form of little patches on the tonsils, uvula, soft palate, or faucial pillars.

Two cases with true diphtheria from an asylum, one appearing like a follicular tonsilitis and the other with an abscess of the tonsil, bring out the difficulty in making a clinical diagnosis. In most of the mild cases in children this was impossible.

The severity of the disease seems to be almost directly in proportion to the extent of the membrane. The difference in cases is very striking. Those of croupous rhinitis, and many in which the disease is confined chiefly to the tonsils and uvula, both children and adults, hardly seem ill at all. Others with throat and nose lined with membrane are very seriously ill from the beginning and usually die

The cause of the great difference in these cases is a very interesting study. It is certainly true that malignant cases usually propagate malignant ones, and mild cases mild ones. It is also true that now and then a severe case has received its infection from a mild one, and more frequently still, mild cases have come from severe ones.

The most plausible explanation seems to be that there is a great difference in the virulence of bacilli from different cases, and also that the degree of susceptibility of individuals varies greatly. Some seem almost to be immune. Whether the greater proportion of children infected is due to their greater susceptibility, or to the fact that they are so apt to put things in their mouths, and that, when carried, their faces are brought directly against that portion of the clothing most likely to be infected, is an interesting question.

In the limited number of cases here examined the effect of the association of other organisms cannot be safely judged. The opinion has been forced strongly upon me that the Loeffler bacillus is the predominating factor. Some of those having given pure cultures of the Loeffler bacilli have been fatal, while others in which streptococci abounded have been very mild. In malignant cases with sloughing membrane the surface is crowded with micrococci and bacilli, but the probability is that they find the dead tissue a good soil for their growth. In

small children the association of the streptococci probably adds to the danger of a complicating broncho-pneumonia.

The temperature has been looked upon as a test by some. It is the general experience of those who have inoculated animals with Loeffler bacilli that the temperature falls soon after, and remains subnormal till death. On the other hand, inoculations of streptococci, when they produce any effect, raise the temperature.

In those cases of diphtheria in which the bacilli alone were present the temperature never rose above 100 F. In those in which the streptococci were abundant some had a high temperature, others a low. For prognosis the temperature was of no value except in children where lung complications occurred.

The marked swelling of the cervical glands and tissues was present only in those cases where other bacteria, especially streptococci were present. In many fatal cases there was no swelling, while some in whom it was marked recovered. In the bad cases, albumin in large amounts usually appeared in the urine. In many mild cases, no albumin was ever found. The deaths occurring some days after all membrane had disappeared from the throat bring out a peculiar danger in diphtheria.

The six cases of membranous rhinitis are of great interest, for it is only very recently that they have been thought to have any relation to true diphtheria. They seem regularly to recover.

[For a detailed description of the plate see end of article in next week's issue.]

(To be continued.)

A NEW OPERATION FOR THE SPEEDY RIPENING OF IMMATURE CATARACTS.[1]

By BOERNE BETTMAN, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE CHICAGO POST-GRADUATE MEDICAL SCHOOL; OCULIST AND AURIST TO THE MICHAEL REESE AND GERMAN HOSPITALS; ATTENDING SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY; PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO, ILL.

In the issue of the *Journal of the American Medical Association* for the first week in December, 1887, there appeared a paper by me on artificial ripening of cataract. I called attention to a method devised for that purpose. I have since then constantly employed this procedure with satisfactory results. Since the subject has attracted the attention of specialists principally, and has not been brought to the notice of the medical public in general, I may be pardoned if I give a brief outline of the reasons which led to, and the short history of, artificial ripening of the cataractous lens. A rule laid down by operators, and observed up to within a few years ago, was not to extract an opaque lens until it was perfectly ripe, and it was only then considered ripe when nucleus and cortex had undergone degeneration.

This state is made manifest by the absence of an iris shadow and by ocular inspection of the cortical layers under oblique illumination.

The crude way of determining maturity of the cataract consists in placing the patient with his back to the light and calling upon him to count fingers (qualitative perception of light) placed within one foot of him. If he is unable to answer correctly and can only determine the direction of the moving hand (quantitative perception of light), the cataract is considered ripe and ready for operation.

Since the introduction of irrigation by Wikeriewicz, Panas, and others, whereby the anterior chamber is washed out with a non irritant solution, the above rule has no longer been adhered to. Many non-mature cataracts are now operated upon and the transparent cortical substance, it is claimed, removed by the flushing method.

I will state right here that I have never employed this method, deeming it wiser, and surely safer, either to await the ripening of the cataract or to hasten its maturity by trituration. Senile cataract ordinarily makes its appearance after the age of fifty.[2] Its rate of progress is extremely variable, requiring sometimes months, more often years. During this period, especially after sclerosis has involved a greater portion of the lens volume, the afflicted individuals are in a helpless condition, cut off from the enjoyment of life, and, what is of far greater importance, forced to resign profitable and life-supporting occupations. At present I have under observation a gentleman where the development of the cataract on one eye has remained stationary for four years. The other lens shows some opaque lines at the equator and a decided blur in the nucleus, which impairs vision very materially.

Various methods have been devised for hastening this condition of slow development. It has been noticed that an iridectomy[1] accelerates the process of total sclerosis; puncturing of the lens with a needle has also been employed, as well as evacuation of the aqueous humor by paracentesis. None of these methods withstood the attack of critical investigations, and it was left to Professor Förster, of Breslau,[2] to devise a method which is extensively employed, and has received favorable notice from a great number of oculists in all parts of the world.

As the action of my procedure is based upon his, the execution only being different, it will be well to enter more fully into an account of his innovation, and for that reason I will quote a few sentences from my former publication[3] relating to Förster's method: "The procedure consists in gently rubbing the cornea, after doing an iridectomy, with the blunt end of an instrument, usually a strabismus hook or iridectomy forceps. The pressure exerted upon the cornea is transmitted to the lens, loosening and splitting the still adherent and semi-opaque cortical fibres. These, in the course of days and weeks, become perfectly opaque." "So long as the cataract is not mature, an operation is contra-indicated. So long as the cortical substance is still firmly adherent to the capsule, extraction of the lens cannot be performed with perfect safety to the patient, for, as Förster correctly states, the remaining layers of cortical substance will imbibe aqueous humor, swell, and give rise to iritis, and other dangerous complications."

Förster warns against rubbing the cornea too violently and squeezing the iris to avoid dislocation of the lens and iritis. He furthermore advises that pressure be made only in the pupillary area and within the limits of the iris coloboma. These very restrictions constitute what I will now consider under the head of objections to the indirect method of trituration.

Objections.—Escape of the aqueous humor after doing an iridectomy is followed by contraction of the pupil. If previously dilated with atropine the contraction is less, consequently the area of lens surface exposed for trituration is limited. Furthermore, the iris intervening between the cornea and lens is subjected to a constant pressure whenever the cornea is triturated hard enough to transmit the force to the lens. The iris fibres, besides being squeezed, are also contracted and relaxed, giving rise to a constant mechanical irritation which may result in an iritis. I had a similar experience in one of my earlier cases which greatly dampened my enthusiasm.

[5] Transactions of the Ophthalmological Society of the United Kingdom, vol. vi., p. 317. At the June meeting, 1890, of the Ophthalmological Society of the United Kingdom, Dr. Snell read a paper upon "Trituration of Cataracts," according to Förster's method. During the discussion which followed, Dr. Hill Griffith (Manchester) stated that he had matured the lens twenty-eight times by the direct method, namely, with a silver spoon, introduced through the corneo-scleral wound into the anterior chamber. Of the 24 cases, no result was obtained in 13; in one, partial dislocation lentis followed, the only mishap he experienced; in 11 maturation was rapidly effected; slight loss of vitreous occurred after one extraction. Good vision was procured in all. He does not refer, however, to my investigations, which were published in 1887.

[6] Reference Handbook of the Medical Sciences, vol. i., p. 800.

call attention to this danger; Jacobson noticed also inflammatory thickening of the anterior lens capsule as a result of indirect trituration.

It must also be remembered that the cornea, as well as the lens is being triturated, which may give rise to epithelial opacity. This danger is greatly obviated by dipping the instrument employed in water or vaseline, and making gentle to-and-fro motions. These various objections induced me to seek a safer method of operation, one which could be just as readily performed and free from the risks which Förster's entails. I therefore practised, as early as 1885, the intraocular method of massage, which, to distinguish it from Förster's, I have called direct trituration.

My method of operating is as follows: After doing an iridectomy the eye is rotated downward with a fixation forceps, so as to facilitate the entrance of the spatula into the anterior chamber, and to permit its free movements in all directions. The instrument employed is such as all oculists use in restoring prolapsed iris. It is a flat, slightly flexible piece of steel. 25 mm. long, and 1 mm. broad, attached to a handle. The blunt surface of the spatula is placed in contact with the lens, gentle but firm to-and-fro motions are made over its surface. The end is slid under the iris on both sides of the pupil and below it, the massage being thus continued over the larger part of the lens. A half dozen to ten strokes will suffice. The spatula is carefully removed, the eye sprayed with a sublimate wash, or more often with a boric acid solution. Two drops of atropine are instilled and the eye bandaged.

Precautions.—Certain ordinary precautions must be observed in direct trituration, to which I have already called attention in my former publication. Not to exert too much pressure on the lens for fear of producing a dislocation. Not to tilt the instrument for fear of lacerating the capsule. The danger of causing dislocation of the lens is not so great as one might imagine, naturally a great deal depends upon the lightness of the manipulations, and I heartily coincide with Förster in believing that whoever can extract a cataract successfully has also sufficient delicacy of touch to perform trituration without injuring the lens.

Results.—Ordinarily no immediate results of the operation are visible. In a few cases, especially in the softer forms of cataract, where the cortex contains broad opalescent striæ, I have witnessed the separation and breaking down of lens fibres under the pressure of the spatula. The mother-of-pearl bands on the surface detach themselves from the body of the lens, split, are forced from their position, and by means of frequent fractures are transformed into a mass of fragments.

In one instance, Case III., formerly reported, the entire appearance of the cortex had undergone a complete transformation twelve hours after the operation. The cortex showed an almost uniform opacity. The less marked cases exhibit a feathery appearance of the former transparent cortex, extending usually from the capsule inward. Sometimes two, three, or more of these foci or opacities are seen, gradually they coalesce and the entire substance is involved.

The length of time required for the complete ripening of the lens varies with the nature of the cataract, and naturally also with the thoroughness of the trituration. At first, fearful of dislocation and rupture of the lens, I contented myself by sliding the spatula over the capsule and only occasionally exerting gentle pressure. As my experience increased I became bolder, and my results became correspondingly better.

I have never seen the least reaction follow trituration. The slight congestion visible a day or two afterward could always be ascribed to the iridectomy which preceded the massage in all cases but two, where I matured the lens without having first removed a portion of the iris. In not a single instance did the bandage remain over the eye more than two days, a practice I usually follow after every iridectomy. Iritis, cyclitis, dislocation of the lens, or other complications which could be regarded as a direct consequence of my procedure, have absolutely never occurred.

The absence of unfavorable symptoms constitute the main advantage of intra-ocular trituration over Förster's method. Another commendable feature is the rapidity with which the lens ripens. In one of my cases, No. 1, Förster's method was employed, six weeks later no effect having been visible, the direct trituration was resorted to and matured the lens in three weeks.

A few years ago my friend, Dr. Starkey, requested me to ripen a lens which had not responded to the indirect method. I gladly acquiesced. The result was very satisfactory, the patient reporting for the final operation a few weeks later.

Criticism.—I am not unconscious of the criticisms the direct method may provoke. They may be formulated under the following heads: Introduction of instruments into the eye; injurious effect of direct pressure of the capsule; prevention of simple extraction.

It may be regarded as an unwritten law, and one adhered to by the ablest men, that the fewer the instruments introduced into the eye the less the danger of complications and infection. However, since the introduction of strict antisepsis the danger is greatly lessened. The instrument, as already stated, is placed in boiling water for a few minutes and then dipped in a boracic acid or sublimate bath; consequently there exists no possibility of infection. Besides, the instrument is smooth and thin, and contains no irregular or sharp edges, preventing any possible bruising or tearing of the tissues.

As for the second series of objections, I can only reiterate that careful and skilful manipulation of the spatula in my hands has never been followed by any untoward symptom. Seemingly the most probable misadventure would be tearing of the suspensory ligament and dislocation of the lens. Such a mishap would surely result in an escape of vitreous during a subsequent operation for extraction of the lens. In two cases only vitreous escaped, due, however, to other causes.

In Case II. the patient was very refractory, and made a sudden movement while my cystotome was passing into the anterior chamber. In removing it I tore the zonula. I entered again and made the peripheric capsulotomy; pressure on the cornea with a spoon resulted in an escape of a small bead of vitreous. This I snipped off and extracted the lens with the greatest ease. The capsule healed, but a rent in the zonula at the upper inner part of the coloboma is still visible.

The second case of loss of vitreous (Case XIV.) was caused by an ineffectual attempt to force a large nucleus through a small corneal wound, which was enlarged on both sides with scissors. Still the lens would not move, when it was discovered that a posterior synechia constituted the hindrance. The lens was removed with a spoon. The eye made a beautiful recovery. A secondary operation made four weeks later yielded V. $= \frac{20}{40}$ with + 11 D.; a small black opening above the opaque capsule marked the tear in the zonula.

It is not my intention to discuss the various methods of cataract extraction. Knapp and Schweiger and others are pronounced in their conviction of the superiority of simple extraction over the old method associated with iridectomy. Graefe and his followers, on the other hand, decry the operation where an iridectomy is not made, and the round pupil preserved. If simple extraction were to become general, it would be argued that trituration of the lens, which I had preceded by an iridectomy, ought to be avoided. In order to overcome this drawback and make direct trituration feasible to the adherents of simple extraction I determined to triturate without iridectomy.

I succeeded in Case V. in ripening the lens in three weeks. The cataract was extracted by the simple method. The iris prolapsed on the second day, however;

I cut it off; the wound healed with a cystoid scar which causes no annoyance. V. = $\frac{2}{40}$ with + 10 D.

In Case XI. I succeeded in reducing V. = to fingers at eight feet to V. = fingers at three feet, within three days. A week later the patient could not count fingers at all. The lens was extracted at the expiration of three weeks, with splendid results.

A round pupil offers no obstacles to direct trituration; the lens surface exposed is naturally much smaller, but since the spatula can be passed under the iris effective work can be accomplished.

In order to avoid pressure on the iris, I had a special instrument constructed for these very cases. The end of the spatula is trowel-shaped one millimetre deep. The slope from the shank to the flat surface of the trowel is very gradual, so as to permit easy entrance through the corneo-scleral wound. When the trowel rests in the pupillary space on the lens, the shank of the spatula is raised above the iris and prevents contact with the latter, at the same time leaving the action of the trowel unrestricted.

Indications.—Not all cases of cataract are amenable to trituration. The hard nuclear cataracts, with a reddish brown reflex, yield least readily; the softer forms, showing broad mother-of-pearl striæ in the cortex, are the most favorable cases.

Dislocated lenses and cataracts, secondary to myopia or other intra-ocular changes, are not to be considered as coming within the range of my method. Neither have I thus far attempted to triturate cases showing a decided reflex from the fundus. In the great majority there was an entire absence of reflex, and in none of them was it possible to obtain even the slightest detailed view of the retina. It has been my practice to operate on only such unripe lenses which show a greater or less iris shadow, and which enable fingers still to be counted at a distance of from eight feet to one foot.

The following records are taken from my private and hospital practice. The clinical histories of a number of my earlier cases were not accurately kept; this will account for the small number reported.

Case I.—Mr. D. C——, aged sixty two. R. E., immature senile cataract; duration fourteen months. V. = fingers at four feet. Projection and perception of light good; iris shadow marked; cortex contains broad striæ. L. E., dislocated cataractous lens, resulting from a fall down the stairs of the hospital. June 1st, triturated according to Förster's method, but as the condition of the cataract did not change I did direct trituration July 13th. A few days later unable to count fingers close to eye, can only determine direction of movements. July 23d, extraction of lens. No reaction. Three days later wound perfectly healed, no injection, bandage removed. Secondary operation two weeks later. V. = $\frac{2}{25}$ with + 10 D. Reads finest print with + 13 D.

Case II.—Thomas S——, aged fifty. L. E., dense band-shaped opacities of cornea; immature nuclear cataract; duration about eleven months. Very few narrow striæ visible in cortex. Counted fingers at three feet. Iridectomy and direct trituration June 13th. Patient discharged a few days later and told to return at the end of three weeks. Early in July vision is reduced to qualitative perception only. Extraction of lens deferred, at patient's request, until October 8th. The zonula of Zinn was partially torn with cystotome, which was rapidly removed from the eye owing to the unruliness of the patient. A small bead of vitreous presented. This was nipped off. Rupture of capsule and delivery followed without any further complications. October 11th, wound perfectly closed; eyeball pale; bandage removed. November 6th, needled for secondary cataract. V. = $\frac{20}{100}$ with + 10 D., an excellent result when the corneal opacities are taken into consideration.

Case III.—John D——, aged seventy-eight. R. E., immature senile cataract. Duration four years. Broad striæ in cortex. Iris shadow marked. V. = counts fingers at two feet. November 5, 1891, direct trituration with iridectomy. No reaction. November 15th, qualitative perception of light; extraction of lens; clear, black pupil. No reaction. November 18th, bandage permanently removed; eyeball pale. Needled, V. = $\frac{20}{20}$ with + 10 D. + 1 D. cyl. axis 90. With addition 3 D. reads finest print.

Case IV.—Christ. H——, aged sixty-two. Immature senile cataract; duration four months; broad striæ in anterior cortex; iris shadow. V. = fingers at two feet. October 8th, direct trituration with iridectomy; no reaction. October 29th, cataract mature; lens extracted, leaving black and clear pupil. Two weeks later, secondary operation. V. = $\frac{20}{30}$ with + 9 D., reads Snellen 0.5 with + 13 D.

Case V.—William H——, aged thirty six; glass-blower. Non-mature cataracts on both eyes. Three months' duration. R. E., sees quite well, able to walk about. L. E., fingers at six feet; marked iris shadow; large amount of transparency of cortex; striæ broad, color almost white. Direct trituration, without iridectomy, November 5, 1891. Not the slightest reaction. November 25th, lens mature, no longer able to count fingers. The lens extracted with ease. No complications. November 28th, iris prolapsed. Iridectomy. Wound healed with a cystoid scar at inner angle. Early in December the cyst was opened with a Graefe knife, iris pulled forward and excised. Wound healed nicely, is but slightly elevated at one point and pigmented. Secondary capsulotomy, done early in January, resulted in V. = $\frac{20}{40}$ with + 11 D.

Case VI.—Mr. H. P——. Senile immature cataract, duration about twenty months. R. E, incipient cataract; able to read. L. E., V. = fingers at five feet. Broad iris shadow, broad striæ. Direct trituration of L. E, accompanied by iridectomy, May 22, 1891. Patient discharged a week later to return in September, not desiring to be operated on during the heat of the summer. Re-admitted in October with an acute trachoma of both eyes. Mr. P—— volunteered the information that with the operated eye he could not discern objects four or five weeks after his discharge. At the date of writing trachoma granules have almost disappeared.

Case VII.—Mrs. G——, aged fifty-five. L. E., incipient cataract. R. E., immature nuclear cataract. Counts fingers at seven feet. Duration about one and a half year. Broad iris shadow, amber-colored reflex. Very few narrow striæ in cortex. April 15th. iridectomy and direct trituration. No reaction. July 1st, extraction of large nucleus. Small quantity of cortex. Capsule thick and white. August 20th, secondary operation. V. = $\frac{6}{12}$ with + 11 D.

Case VIII.—Miss R——, aged sixty. Non-mature nuclear cataract on both eyes. R. E., V. = fingers at fifteen feet. L. E., V. = fingers at four feet. Duration, L. E., about two years. Amber-colored reflex; broad iris shadow; opalescent bands in upper onter part of cortex. October 9, 1890, iridectomy and direct trituration. Five weeks later, little change. January 3, 1891, extraction of large nucleus, very little cortex. V. = $\frac{6}{9}$ with + 10, reads Snellen 0.5 with + 14 D.

Case IX.—Mrs. F——, aged sixty-five. Nuclear cataract both eyes. R. E., lens dislocated. L. E., V. = fingers at five feet. Duration two years. Amber-colored reflex; sclerosis almost total; very few striæ visible. June 3, 1891, iridectomy and direct trituration. August 25, 1891, V. = 0; extraction of hard lens; very small quantity of opaque cortex. Pupil black. Two days later, hemorrhage in anterior chamber covering entire pupillary field. This gradually absorbed, and at the expiration of two weeks she was discharged with V. = $\frac{6}{36}$ with + 11 D. The secondary capsulotomy has not been made at date of writing.

Case X.—Mr. H. D——, aged fifty-eight, consulted me for the first time in October, 1889. He had an unripe cataract of both eyes; his vision was very much reduced. The left cataract was more advanced than the

right. I proposed the operation of trituration, to which he would not accede, however. He returned in September, 1890. The left cataract had progressed somewhat, but was far from ripe. The iris shadow was extensive, and but a few broad striæ were visible in the anterior cortex. He counted my fingers at a distance of eight feet. A dim reflex was obtained with the ophthalmoscope. I made an iridectomy and triturated the lens September 23d. No reaction followed. Two weeks later he was able only to determine the direction of the moving hand. November 30th I extracted the lens. A week later he was discharged from the Michael Reese Hospital. A subsequent capsulotomy was soon performed, followed by V. = $\frac{6}{9}$ with + 11 D. With + 15 D. he read the finest Snellen type.

Case XI.—Mr. A——, aged fifty-one, kindly sent to me by Dr. MacArthur. R. E., incipient cataract, able to follow his vocation as salesman of paints. L. E., non-mature cataract. Duration, one year. Counts fingers promptly at eight feet. Dim reflex from fundus through lower part of lens. Iris shadow. Broad glistening bands of opaque striæ in cortex. December 28, 1891, direct trituration without iridectomy. Absolutely no reaction. Discharged three days later. V. = fingers with difficulty at two feet. Made a trip to St. Paul in pursuance of his calling, but was obliged to return home after a few days, owing to his poor vision. January 25th, V. = 0. Extraction of lens followed by rapid, uncomplicated healing. V. = $\frac{20}{40}$ with + 11 D. Secondary operation has not yet been made.

Cases XII. and XIII.—Mrs. B——, aged sixty-two, L. E., incipient cataract. R. E., immature nuclear cataract, two years' standing. Amber colored reflex. Iris shadow. Counts fingers at five feet. August 6, 1889, iridectomy, direct trituration. September 10th, vision reduced to qualitative perception. Iris shadow still present, and superficial layer of cortex apparently transparent, V. = 0. October, 1889, extraction of lens in bulk. V. = $\frac{6}{9}$ + with 10 D., reads Snellen test type with + 14.

November 19, 1890, iridectomy and direct trituration of left eye, the vision of same having been $\frac{4}{200}$. The patient returned to her home and passed through a severe illness, lasting several months. She wrote to me in May that she had almost regained her strength, and that the eye was ready for operation, not being able to count fingers close to her face. I advised her to wait until October, 1891, when I removed the lens. Recovery was rapid; result after doing secondary operation excellent. V. = $\frac{6}{6}$ with + 10 D.

Case XIV.—James S——, aged sixty-five. Under observation two years. R. E., cataracta incipiens, sees sufficiently to perform ordinary work about the house. L. E., cataracta non-matura, almost stationary during this period. September, 1889, V. = fingers at ten feet. October, 1891, V. = fingers at eight feet. Broad iris shadow. Lens grayish in color, greater part of anterior cortex transparent. October 15th, iridectomy and direct trituration. Five days later can determine the direction of the moving hand, V. = 0. November 21st, Graefe's linear incision made with the left hand. Repeated attempts to deliver were ineffectual. Wound enlarged with scissors on both sides. Again failed to extract cataract. Vitreous now presented in the corneal wound. Entered with a spoon and quickly removed the lens, which was adherent to the iris. No reaction followed, and the patient was discharged from the Chicago Charity Hospital two weeks later, with a secondary cataract. A capsulotomy made December 21st resulted in V. = $\frac{20}{40}$ with + 11 D.

If I add to these clinical histories three previously published, I have seventeen well observed and authentic cases from which to draw a few deductions. All, with but one exception, Case V., were senile cataracts, and can be brought under two distinct headings. Lenses with soft cortex and lenses with large nuclei and very little cortex.

Of our Cases I., III., IV., V., VI., IX., X., XI., XIV., and II. and III. in the first publication belong to the first series, the remainder to the second.

A striking difference presented in these cases is the shorter time required for the maturescence of the softer cataracts. In none of the first series, with the exception of Case X., did more than four weeks elapse between trituration and extraction of the lens.

Ordinarily the time was even shorter. The second series does not show so favorable a record, not less than two months being required for the ripening of the more sclerosed lenses. Even this period must be considered short when compared with the natural, slow development of this form of cataract. These results are not in accordance with Förster's observation, who states that the hard opaque nuclei are more amenable to trituration. Another noteworthy feature was the almost constant absence of transparent cortical substance during the removal of the lens. This greatly facilitated the operation and lessened the dangers of subsequent iritis and other forms of infection.

Pressure on the capsule produced in several cases a thickening of the membrane. This, no doubt, was due to a proliferation of the epithelial lining of the anterior capsule similar to that observed in capsular cataract. The thickened capsule yielded as readily to Knapp's knife as did the thinner ones, and did not affect the ultimate vision.

In only two cases was direct trituration practised without a preliminary iridectomy. The results of the operation were immediate and pronounced, and demonstrated conclusively that iridectomy is not a necessary factor to the effectiveness of the intra-ocular method.

The vision obtained after extraction of the cataract was good in every instance, in one case only, No. II., was it less than $\frac{20}{40}$, and here the dense corneal opacities accounted for the apparently poor result, V. = $\frac{20}{80}$. The great majority obtained V. = $\frac{20}{30}$, and three even succeeded in reading the last line of Snellen's test types—normal sight. A more striking proof of the safeness of direct trituration can hardly be adduced.

39 Washington Street, Chicago, Ill.

Antirabic Inoculations for Epilepsy.—What connection can there be between a neurosis like epilepsy and a disease distinctly traceable to the entrance into the blood of the microbe of rabies? Vulpian long ago stated that epileptic attacks were due to an exaggerated excitability of the medulla oblongata, and we know that the variable incubation period of hydrophobia is due to the variability of the time taken by the migration of the special microbe from the seat of inoculation to the medulla. Once arrived there, the explosion occurs, and all the characteristic train of symptoms peculiar to the disease appear. In 1891 two young epileptics who had been bitten by rabid dogs were treated at Pasteur's Institute. The treatment was successful; but what was more remarkable, the epileptic attacks to which they had been subject had disappeared. Struck by this phenomenon, M. Pasteur mentioned the circumstance to M. Charcot. Recently M. Charcot sent to the Pasteur Institute an inveterate epileptic aged twelve years, who had been unaffected by all forms of treatment. Somewhat attenuated inoculations were employed, with the effect of determining, in six days after the commencement of the treatment, the total disappearance of the attacks, which had been hitherto extremely frequent.—Paris Correspondence of *The Lancet*.

The New Medical Education.—Professor Struthers, of Aberdeen, has written two interesting articles on the new medical education. He advocates less lecturing; especially he denounces the system of taking out a course more than once. He strongly recommends the further use of laboratories, and he deprecates the introduction of anatomy, except in its very elementary forms, before the first professional examination is passed.

A NEUROLOGICAL OUTLOOK.[1]

By CHARLES L. DANA, A.M., M.D.,

NEW YORK.

THE speaker began with an account of the organization of the Association, which he said took place in New York City in 1875. Eleven members were present and eight papers were read. The Association now has seventy-five members, and there was a list of forty papers on the programme. The Neurological Association was the third in the list, chronologically, of national organizations of specialists. Since its birth twelve new specialties had developed. The speaker paid a warm tribute to the character of the late Dr. William R. Birdsall. Entering upon the formal part of his Address he said :

The distinguishing characteristic of the addresses before this Association has always been their briefness, and I shall not depart from a custom so well established. Some of my predecessors have told the story of the scientific work accomplished by our society, others have suggested lines of work which we might profitably pursue in the future. I propose to dwell for a few moments upon those particular phases of neurological science which are just now most keenly interesting us, and those lines in which new developments are promised.

Clinical Work.—The subject of multiple neuritis has become a little worn and frayed at the ends ; we are yet far from knowing its ultimate pathology, and there are many interesting clinical phases which have not been mastered, but the keenness and zest of our inquiry along this line has little waned.

Muscular dystrophies and muscular atrophies have engrossed great attention and received from the hands of several of our members most important contributions. This subject is not yet closed, but we have a knowledge of it now vastly more complete, systematic, and satisfactory than was possessed even five years ago.

The enthusiasm with which we plunged into brain localization and pointed out the areas for the surgeon to operate has perhaps received a little check. The halo which surrounded cerebral surgery, luminously adorning the anatomical landmarks used in cranial topography, has lost some of its lustre. Even the hopelessness of microcephaly has failed to revive, except temporarily, our lively interest in the possibilities of what the surgeon can do in aiding our therapeusis. We shall work on here patiently, but not with the hopefulness felt five years ago. The great achievement of spinal surgery is to have shown that the opening of the spinal canal is relatively safe. With this basis to start upon, something may be expected of spinal surgery, which in the past has had a few real triumphs and many failures.

We have been quarrelling annually over the interesting but somewhat transcendental problems of syringomyelia, analgesic whitlows, and the differentiation of cutaneous sensations. There is no doubt whatever that such discussions stimulate investigation and promote more thorough clinical work, although in the western hemisphere the number of authentic cases of these diseases is extremely small.

Progress of Anatomy.—In no department of neurological science, however, have there been results so far-reaching in importance and so absorbing in interest as in that of the finer anatomy of the nervous system Through the help of the Golgi stain and its modifications by Cajal, through the labors of Kölliker, His. Waldeyer, Edinger, Lehassek, Marchi, and others, entirely new views of the intimate structure of the nervous system have been apparently established. The discovery of the origin of the sensory tracts of the cord from the posterior spinal ganglia is not the least of these, and is alike important clinically and remarkable as an illustration of exact anatomical demonstration. The fact that each nerve-fibre is but the prolongation of a nerve cell process has been made more indubitable ; but besides this, it has apparently been shown that each nerve-fibre gives off in its course branches, or "collaterals," which put the individual fibre into connection with other parts in a way not before suspected and not yet clearly understood. Still further, it has been shown that each nerve-fibre ends in a fine brush work of nervous filaments, which surrounds the cell to which it goes in a kind of basket-work that just touches but has no anatomical continuity with it. One nerve-cell with its process is never connected anatomically with another, but just comes near enough perhaps to titillate and touch it off Waldeyer has coined a new word for the nerve-cell, fibre, and end-brush. He calls it a nerve unit, or "neuron." The word will fill a place in neurological nomenclature.

New stains and improved methods of research have also led to the discovery of new forms of cells in the cortex of the brain, and to a better knowledge of the marvellous net-work of fibres in this area. Studies here in the future will surely throw fresh illumination on the problems of psychiatry and psychology.

Pathology.—Not very remotely connected with this subject of anatomy is one which has for some time deeply interested myself and others—the true nature of many of the so-called inflammatory and degenerative processes. There can be no question that the older terms so commonly employed, such as chronic myelitis, anterior poliomyelitis, parenchymatous inflammation, encephalitis, have given a wrong idea of the true nature of the pathological changes which underlie them. The term sclerosis has been used to indicate a degeneration which is primary, a degeneration which is secondary, and a simple reparative process the result of an acute destruction of tissue. The part that the neuroglia tissue plays in such scleroses, aside from the connective tissue, has surely been much misunderstood and is not yet at all definitely settled. I am sure that in future, when the new pathology of the nervous system is written, while the old terms may be retained for their convenience, it will be made clearly understood that the "itis" does not by any means represent an inflammation, or the "sclerosis" indicate always the same thing. I do not know that we can sharply distinguish processes which are degenerative from those which are inflammatory, but in those which are typical it is evident that the distinction is extremely great. The inflammation has to do with the connective tissue, blood-vessels, and lymphatics ; it is the reaction of the organism to an irritant, and it is an expression of the attempt on the part of nature to rid itself of a noxious substance : it is essentially conservative and reparative. The degeneration is a process which seems allied to premature death; it affects the parenchyma first, and this tissue dies beneath its subtle and malignant influence. There is no conservative function connected with it, so far as we can see. The process is a progressive and continuous one, and eventually fatal. So far, its ultimate cause and its cure have entirely evaded our powers, and there is no greater reproach to neurology, in my opinion, than these facts What more painful spectacle is there than the steady onward progress of locomotor ataxia, with its ferocious pains ; or what more pitiable than the deathward march of a patient with progressive muscular atrophy or a bulbar palsy? Standing before such cases we feel always the limitations, the helplessness of our science, and perhaps some mortification, even resentment, at the powerlessness of our art. It is, therefore, in my opinion, along the line of the degenerative diseases that we need to spend for some time our very greatest efforts. We should try and learn, not so much the clinical manifestations of degeneration, which have become almost tiresomely familiar, but the ultimate cause. What does it? why does it so persistently progress? And the radical cure—is there nothing in art or nature which seems for more than a moment to stay its progress? It does seem to me possible, if not probable, that there is at the bottom of these troubles some toxine, evolved perhaps from an infection, perhaps from some dyscrasia, which selects now one part

[1] Abstract of the Presidential Address delivered at the Seventeenth Annual Meeting of the American Neurological Association.

of the nervous system, now another, for particular destruction.

Therapeutic Outlook.—If this be so, there must be somewhere in the storehouse of nature an anti-toxine which will prevent its progress or can confer immunity upon the individual. If we can find in the range of bacteriological knowledge or experience a bacillus whose poison will produce a locomotor ataxia or a polio-myelitis, it may be possible, through some modification of it, to obtain a virus which will secure a happy therapeutical end. The rewards will be great for him who discovers such a substance. A possible immortality, which its discovery would secure, to say nothing of the immediate rewards to himself and humanity, should be a sufficient stimulus to all of us to work in this direction.

But, after all, such speculations as these are perhaps only fanciful. It may be that in some persons certain cells or systems are born to die prematurely. Meanwhile we must work patiently and faithfully, building up little by little the framework of that edifice which will eventually be the perfected science of neurology. Such an edifice we can, here among ourselves at least, believe will be by far the most glorious of any which adorns the circle of the medical sciences.

ICE SCIENTIFICALLY APPLIED OVER THE SPINE IS AGREEABLE AS WELL AS BENEFICIAL TO THE PATIENT.

By B. O. KINNEAR, M.D.,

NEW YORK.

An objection frequently advanced to the use of cold over the spine, and a formidable one to combat, on account of its universal prevalence, is the impression that it will "chill the body"—"it is heroic"—and must be exceedingly disagreeable to the patient.

The real fact, however, is that with people who already suffer from cold sensations, cold or cool legs and feet, cold arms and hands, or cold body, no known remedy acts more quickly, powerfully, and pleasantly to overcome this abnormal condition. This truth is now proven beyond controversy, so far as my own observation is concerned. From the results arrived at in treating persons so affected, I am convinced that the body, arms, and legs may be permanently warmed by ice placed over the spine in bags four and a quarter inches wide in the adult, and the strength of the patients largely and permanently added to, even though they may have suffered for years. The difficulty arising to prevent physicians and the public from acceptance of this verity is a simple one.

It is practically true that cold applied locally upon the surface of the body, except during the process of inflammatory diseases or active congestions, will, and does, chill the individual; and thus it is argued that cold over the spine must inevitably produce the same effect.

Such a conclusion is totally erroneous. My belief is, that a cool or cold surface of the body or extremities not due to some immediate local cause, such as exposure to cold, etc., but forming a constant factor in the daily life of the individual, is the resultant of an increased circulation, greater than normal, of blood, within certain nervous centres—the sympathetic ganglia—situated close to the spinal cord; and whose chief function for many years has been declared to be, by many eminent physiologists, that of contraction of the arteries. These knots of nervous material, or vasomotor centres, having their function increased by the stimulation of more arterial blood than is required for their healthy action, issue more forcible nervous currents through their nerves to the elastic and contractile coats of the smaller arteries in the body and extremities, causing in these vessels a powerful closure.

This contraction diminishes the usual and normal amount of blood in the parts controlled by the centres, and we have, as a consequence, cold body, arms, or legs, according to the centres involved.

Now if the circulation is decreased permanently in any portion or portions of the body, we have lessened nutrition and physical prostration in the individual, as most graphically presented in people suffering from the so-called nervous prostration, with cold arms and legs almost a constant factor.

This disease, in the writer's opinion, should be properly termed physical prostration, due to central vasomotor stimulation, through which increased energy the blood is largely shut off from the whole surface of the body and muscular apparatus of the extremities.

Now, when such a state results the bulk of the blood is confined to a narrower circuit, viz., to the internal organs; therefore, such patients are liable to take cold easily, and to sudden congestions of the bronchi, lungs, liver, uterus, etc., but are especially subject to nervous disorders, owing to the pressure and stimulation of an undue circulation within the brain and spinal cord. In his work on "Neuralgia and Kindred Diseases of the Nervous System," page 314, Dr. John Chapman, of Paris, says: "Were I to adduce all the evidence in my possession that ice applied along the spine, in those cases in which it is therapeutically desirable, is agreeable, soothing, and refreshing, I should fill a long chapter with this evidence alone.

"Many persons shudder at the bare idea of having a column of ice placed along the back, and think that were it continued there for a moderately short time the discomfort would be extreme; that its continued use would be followed by more injurious results, and in any case the remedy would be worse than the disease. These suppositions, however, are not justified by experience, which, in fact, completely contradicts them."

Again: "With reference to the sensations produced by the spinal ice-bag, my readers must bear in mind that it is designed not for the healthy but for the sick, and only for those sick persons in whom has become established precisely that morbid condition of the circulation of the blood in the nervous centres which the application of cold is of all agents the most capable of subduing.

"Hence in these cases, and in these only, inasmuch as the spinal ice-bag subdues a morbid condition in the very citadels of life, a condition in which the phenomena of the disease in question originate, and inasmuch as the cold restores the circulation of the blood in those nervous centres to its normal state without contaminating or embarrassing the system with any medicines, it seeems, *à priori*, that such physiological changes must inevitably be accompanied with sensations of comfort and pleasure, as experience proves them to be."

The amount of evidence I could adduce from Dr. Chapman's writings, as to the soothing and pleasant effect of ice to the spine, when it is rightly used, is very large, but chiefly confining the subject to my own experience the testimony is quite conclusive.

Only two days ago a lady, who has suffered now for several years from acute mental as well as physical hyperæsthesia, accompanied by constantly cold legs and feet, said to me: "Since I used the ice bag my legs and feet have become much warmer, my head is much clearer, I am less irritable, the application at the time quiets and soothes the unremitting restlessness to which I am subject; I become sleepy, and to-day, when a sudden and loud noise was heard, which would usually make me jump, I did not mind it at all, and my husband said to me, 'Why, what has become of your nerves?'" This patient has been under treatment only three weeks. In the case of a patient treated some years ago in Boston, suffering with the so-called American cholera, being almost in a state of collapse—the legs blue up to the knees, and the arms to the elbows—the application of ice over the spine stopped both the vomiting and purging at once, thoroughly warmed the body, and restored a natural redness to the limbs in an hour, drawing the following exclamation from the pa-

tient: "Doctor, this is the most comforting thing I ever felt." One lady remarked: "I would not go anywhere without my ice-bag. Whenever I am tired, or nervous, or cannot sleep, I put it on, with immediate relief and comfort." Another said, "Why, it is not cold at all! it warms me!"

A patient whom I treated for mental delusions, thinking her friends her enemies, and who completely recovered, spoke as follows, "The bag has relieved me from all those disagreeable 'feelings' from which I suffered, and is very soothing." A patient treated in Cambridge, Mass., afflicted with such a cold body that in the hottest summer weather he slept under several blankets, was wholly relieved of the condition in six weeks, as well as from terrible nervous suffering, informing me that "he felt like a new man."

I have often had hysterical patients quieted in a few minutes by the bag over the spine, falling asleep, and frequently remarking afterward: "How delightful! how comforting!" One man, suffering with general eczema and also with cold feet, several times voluntarily expressed himself thus: "When the bag is on, not only does it at once relieve the intense itching and burning of the eczema, but I can feel the blood rushing into my legs and feet, so that they become at once warm and comfortable." I have myself used the bag frequently, especially when worried over difficult cases, or when anxious from any other cause, with immense comfort and relief, being enabled to exercise a more accurate judgment in decision, owing to the mental quietude which results, this calm being due to a withdrawal from the brain of an excess of blood, which is almost invariably present in states of mental excitement, according to my observation since using this system.

Case I., reported in my article on "Neuro-dynamic Medicine," published in the *Boston Medical and Surgical Journal* some years ago, reports: "I have been sleeping from the first of the year an average of from five to seven hours per night. All the disagreeable nervous symptoms that so much distressed me, after any exertion, have gone. My lower extremities are as warm as a baby's." This patient was so nervous and irritable that he could scarcely bear to be looked at without anger, and his legs and feet were so cold that they felt precisely like those of a corpse. He had also been in a terribly sleepless state for two years.

Never have I known the ice-bag to be disagreeable to any patient, unless applied over the wrong sections of the spine, or when there was some diseased condition, which, either permanent or temporary, prevented the ice from producing the effect intended upon the nervous centres or those portions of the body controlled by them. When in any case the beneficial effects of the remedy cannot be obtained, the sole explanation is that some organic disease is present. The treatment of such conditions is separately considered in Chapman's system. In a handbook of this method, soon to be published, particular directions will be given for the special mode of application, as well as the dangers to be avoided, in each individual disease.

Hundreds of people have assured me that the effect of the ice, when expertly used over the spine, is agreeable, soothing, and beneficial, and they who most dread its application, namely, those who are always endeavoring to keep warm, are certainly the very ones who obtain the most benefit, who are warmed and comforted, relieved and quieted.

A few extracts from Dr. Chapman's cases, reported in his work on "Neuralgia," will not be out of place:

"Dr. Moorhead, relating his own experience, Case XXVII., says: 'The ice-bag proved most grateful.'

"Another medical man (Case XXVIII.) writes: 'One thing has struck me, viz., the liking that sensitive, chilly patients have for the cold bag to the spine, although frightened to think of it before they make trial.'

"Dr. Druitt remarked: 'There was no mistaking the testimony of the patients that those results had been most beneficial.' (He was referring to cases of epilepsy and paralysis treated by Dr. Chapman.)

"Case X.: 'Found the ice pleasant.'

"Case XXIX.: 'I do not think I shall ever be able to do without it; it is so comforting.'

"Case XL.: 'It is very agreeable.'

"Case LXV.: 'The ice was quite refreshing.'

"Case LXXVI.: 'I can sleep any time in the daytime now; I fancy the ice draws you to sleep.'

"Case XCV.: 'I like it; it braces me up.'"

Among those upon whom the ice-bag has been used understandingly there is but one opinion, and that is, that ice used over the spine to relieve the states referred to is quieting, restful, refreshing, and invigorating.

46 West Seventeenth Street.

Progress of Medical Science.

Treatment of Dysentery. — Drs. Lardier and Pernet recommend salol and iodoform in the treatment of dysentery; the former in doses of four grains, suspended in mucilage, the latter in quantity of four to six grains daily, combined with opium, in capsules. For the relief of tenesmus, warm boracic acid enemata, and in obstinate cases suppositories of cocaine and opium, were found beneficial.—*The Canada Lancet*, May, 1892.

Habitual Constipation.—Constipation in infants is best treated, according to Karnitsky, by abdominal massage, and may be cured without the aid of purgatives. The younger the child the more readily is the cure effected, though here mild manipulation and short séance is the rule. Three to ten minutes' massage is usually sufficient for any case.

The Pneumococcus in Cerebro-spinal Meningitis. —Dr. Ghika (*Bul. de la Soc. Anat.*, February, 1892) relates the case of a woman who died in hospital, three days after admission, with typical signs of cerebro-spinal meningitis. There was a family history of phthisis, and patient had formerly shown well-marked symptoms of this disease. On post-mortem examination pronounced congestion was found at the base of both lungs, together with atelectasis. At the apices were evidences of old tubercles, and in the right apex a focus of cheesy matter. The cerebral meninges were also congested, and small purulent foci existed over the pia mater as well as on the convexity of the brain, etc. Pus was demonstrated along the Sylvian artery, on the right side, and in this pus pneumococci were found present, although the lungs showed no signs of pneumonia. There was also congestion of the meninges of the cord, and over the posterior portion of the lumbar cord another large purulent focus was discovered. Cultures of the pneumococcus obtained from the congested lungs appeared extremely virulent. The author believes that the pneumococci which determined the congestion of the lungs also caused the meningitis.

Caloric Epilepsy.—Dr. Benedikt relates the case of a lad of fifteen, who from one to several times daily would have an elevation of temperature, attended with loss of consciousness whenever 42.4° to 43° C. were reached. As the attack, which lasted from ten to thirty minutes, came on, the patient assumed a staring expression and invariably murmured the word "robber." The pulse-rate never exceeded 104 per minute. As soon as consciousness returned there was always complaint of contraction of the nuchal muscles, prostration, and visual hallucinations. There were no cerebral symptoms during the intervals. Moderate splenic enlargement, slight albuminuria, and increase of white blood-corpuscles were found. After cautery points over the coronal suture, and sodium iodide, the fits gradually ceased. The author looked upon the case as one of microbic or ptomaïnic intoxication. —*The British Med. Journal, Epitome*, May 14, 1892.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PROGRESS OF THE CHOLERA.

THE latest cable despatches bring the news that the cholera has certainly appeared in Moscow, although the authorities continue to deny that any cases of the disease have occurred in that city. It is, however, of little consequence what the Russian officials admit or deny, for nobody looks to the government returns as even approximately indicating the actual condition of affairs. The only other source of information, and the one upon which the outside world is forced to depend, is in the telegraphic reports of newspaper correspondents, and as these are subject to revision or suppression by the censor, it is evident that we know little concerning the actual extent to which the disease prevails.

The first reports of the present outbreak which came to us were from Meshed, in Persia, a resort for Mohammedan pilgrims second only in importance to Mecca. The presence here of the disease in epidemic form was concealed as long as possible by the Persian authorities, and it was not until the pilgrims began to disperse, taking the disease with them as they went, that the true state of affairs was ascertained. Even then it might have been possible to keep the scourge out of Europe, had it fallen to the lot of any country but Russia to guard the entrances. It was along the line of the Trans Caucasus railroad that the cholera advanced, the feeble efforts of the inane Russian sanitary authorities to keep it back being without the slightest effect.

The first city attacked was Baku, an important petroleum centre on the Eastern shore of the Caspian Sea. Thence the disease advanced to Astrakhan, at the delta of the Volga River which empties into the Caspian near its northern extremity. At this season of the year there is a very active traffic on the Volga, steamers ascending the river as far as it is navigable. As was to be expected from the fact that practically no quarantine regulations were enforced, the cholera ascended the river with the steamers, appearing successively at Saratov, Samara, Simbirsk, Kazan, and finally at Nijni-Novgorod, the seat of the great annual fair.

From this point to Moscow, by way of Vladimir, is a distance of about 250 miles and the communication between the two places is constant and extensive.

There is another route also by which cholera is approaching Western Europe, and that is by the Black Sea. Taganrog, Rostov, and other towns bordering on the Sea of Azov have been invaded, as have also several places in the Crimea.

The Austrian and Prussian officials are, however, thoroughly aroused, and are taking the most stringent measures to arrest the progress of the disease at the frontier. Special barracks for the frontier guards have been erected, and every person crossing the border is subjected to a rigid medical examination.

It is an encouraging sign that, despite the favoring conditions furnished by the personal uncleanliness of the Russian peasant, and the absolute indifference and inefficiency of the Russian sanitary authorities, the cholera has progressed so slowly. Making all allowances for suppression of the truth by the officials, it is evident that the mortality has not been excessive, and we may therefore be allowed to believe that the disease exists in mild form, and to hope that the epidemic may not increase to such overwhelming intensity as to make the exclusion of the disease from Western Europe an impossibility.

As to the danger of an invasion of this country, we think there need be no apprehension. Sanitary science is not as it was thirty, or even ten, years ago, and we believe that, even should the disease make its appearance in the countries of Europe bordering upon the Atlantic, it will be possible to keep it out of this country. The Marine Hospital Service is alert to detect any cases among immigrants, and New York, which is the most exposed of all American ports to the disease, has a quarantine which ought, and doubtless will, see that no case of cholera enters America through this channel.

THE CAUSE AND TREATMENT OF GRAVEL AND THE URIC ACID DIATHESIS.

IT is with a certain sense of weariness that we pick up a new contribution to the subject of uric acid, gravel, and gout. Our experience in the past is that such essays all begin with learned chemical formulæ and end in exercise and potash. Sir William Roberts, however, touches no subject which he does not adorn with the results of careful research and lucid reasoning, and we have perused his Croonian Lectures on the Chemistry and Therapeutics of Uric Acid, Gravel, and Gout with more than ordinary fruitful results.

Sir William gives us a historical introduction which we can pass by with simply the remark that, in this country at least, the work of Bence Jones has not been so unappreciated as he seems to think. Regarding the chemistry of uric acid and the urates, the results of Dr. Roberts' studies show these facts: That there are three orders of uric acid salts; that in addition to the neutral urates and biurates, which have long been recognized, there exists a third order, namely, the quadriurates, which in reactions and chemical constitution differ widely from the other two; that the neutral urates, from their mode of origin and reactions, cannot be regarded as having any possible concern in the vital history of uric acid; that the biurates, although known pathologically as constituents of gouty concretions, are not really known to us with certainty as physiological constituents, either of the blood or of the urine. On the other hand, Sir William shows that the quadriurates existed normally in human urine, and in the urine of birds and serpents; that when uric

acid is brought into relation with the bodily fluids—with the blood, lymph, and synovia—it enters into solution in the first instance, not as a neutral urate, nor as a biurate, but as quadriurate. From all these considerations it would appear, says the lecturer, that whenever and wherever uric acid exists in the healthy organism, it exists exclusively as a quadriurate. The quadriurates may therefore be regarded as being in a special sense the physiological salts of uric acid, and as constituting the only form in which uric acid subsists in the living body in the normal state.

This is an important starting-point. Dr. Roberts then goes on to show that uric acid is precipitated as a biurate in gout *this* side of the kidney, while it is precipitated as uric acid crystals *that* side of the kidneys in gravel. He considers the two disorders by no means identical. Taking up the subject of gravel, he finds this due to the precipitation of uric acid in the renal and vesical urine. The causes of this precipitation are the degree of pigmentation of the urine, the proportion of salines, the percentages of uric acid, and, above all, the grade of acidity of the urine.

Turning to the subject of treatment, Dr. Roberts discusses first that of gravel, which he considers "a primary vice of the urinary function." Since pigments in the urine lessen the tendency to the precipitation of uric acid, it might be thought that something might be done in this direction therapeutically. The lecturer, however, thinks this field unworthy of any effort. As to the deficiency in salines, the evidence points strongly to the suggestion that the subjects of gravel should be advised to take habitually with their meals as much culinary salt as their palates will tolerate. "I may also remind those whose lot it is to practise among the children of the poor, or among the rice-eating populations of tropical and sub tropical countries, that it would be well. in cases of gravel, to see that the patient's food should contain an adequate proportion of articles rich in saline materials, that is to say, of milk, meat, fish, eggs, and salads."

As to the excess of uric acid in the urine, Dr. Roberts believes it to be not necessarily a matter of importance. This is contrary to the ordinary view, which holds that the occurrence of uric acid gravel depends simply on an excess of this substance in the urine (so-called uric acid diathesis). This assumption pervades the entire argument of most writers on gravel, and dominates all their plans of treatment. It is only partially true. It is on this theory that the various and contradictory systems of diet have been built up. As the outcome of his experience Dr. Roberts concludes: That persons who are subject to uric acid gravel, and who are also troubled with a large appetite, should seek to allay their cravings and to lessen the intake of nitrogenous material by the free use of farinaceous articles of food with salads, fruit, and garden vegetables, all of which are comparatively poor in albuminoid constituents.

The excessive acidity of the urine he regards as the most important matter from a therapeutical point. It is advised that the patient take a single good dose of citrate or bicarbonate of potash at night, so as to prevent the tendency to increased acidity during fasting hours and sleep. The patient should not go long without eating, that is, he should not fast from breakfast till late in the day, as is done by some. The use of alkaline mineral waters is of course indicated. The treatment of gravel is a preventive one. Dr. Roberts has no faith in the solvent properties of any mineral waters, and he does not deign to mention piperazin.

THE SPITTING HABIT.

Much good has been accomplished in New York, Pittsburg, and other cities through the labors of societies of public-spirited women organized for the purpose of improving the methods of street cleaning and garbage removal. We publish with pleasure in another column a letter from the Secretary of one of these organizations in Pittsburg, recounting the further good work accomplished by its members in repressing the spitting nuisance. As we have before pointed out, apart from the question of abating a nuisance, there is an important hygienic side to these efforts, for it is well known that more than one disease is spread in great measure through the sputum. We are glad that the ladies of Pittsburg have taken up the combat against this disgusting and dangerous habit. We welcome them as powerful allies in this good cause, and we hope that they may soon have equally zealous imitators in every other city of the country.

THE MEDICAL SOCIETY.

It looks as if the old fashioned Medical Society meetings were beginning to lose their ancient and pleasing characteristics In the volumes of transactions laid upon our tables we find every year fewer of the marks of the presence and influence of the fathers; the address of welcome, the response; the remarks to the ladies; the annual oration by the local statesman; the long report of the committee on ethics, and prizes, and necrology; the colloquial and extended discussions, with here and there a paper containing the report of a case; the complicated parliamentary disturbances, and the flowing farewell of the president. Many of these features are changing; papers are increasing in number; there is some impatience over the long talkers; the easy-going way in which the meetings went along is giving place to the present tempestuous methods of rushing and rustling. The paper must be short, the discussions shorter; and the more there is on the programme, the more successfully scientific is the meeting. The social features, to be sure, are not neglected, but they are set apart and done by schedule also. One must be scientific from ten till five, and sociable from six till eleven. During the remainder of the time he feels like resting, and he generally returns home exhausted by hard listening, heavy eating, and a general excess of medical papers, social indulgences, and an unsterilized water-supply.

We are not going to admit that the older way with its atmosphere of leisure, somnolence, hospitality, and ease was the better one. There was less science then, less evidence of progress, of mental activity, and we may add, less commercialism. But the modern way is not perfect. It tries to do too much, and wastes much energy in the effort. Medical societies have two distinct functions, the advancement and unification of medical knowledge, and the promotion of mutual acquaintance and good-fellow-

ship. It is in regard to the first point that the failure is most lamentable. The reading of papers which will soon appear in some medical journal surely does not promote science. It can only do so by eliciting discussion and comments. It is here that our societies fail, and that improvement must be made.

News of the Week.

Professor Peter Wendover Bedford, editor and founder of the *Pharmaceutical Record*, died July 20th at the Profile House, White Mountains, from apoplexy. Professor Bedford was born in Johnsville, Dutchess County, N. Y., August 1, 1836. In 1858 he was graduated from the New York College of Pharmacy. In 1866 he established the *Pharmaceutical Record* and became its editor. Professor Bedford was Secretary of the College of Pharmacy, and was also professor of pharmacy in the college.

A Small-pox Scare.—Considerable alarm was created last week among the summer visitors to Block Island, by the occurrence of some cases of small-pox among the servants of one of the hotels. The hotel was immediately quarantined, and no new cases of the disease have developed; but many of the guests have been frightened away from the island, and it is probable that the season, which promised to be a very successful one, has been ruined.

Arsenical Wall-papers in England.—*The Lancet* has had a special analytical commission sitting on this bugaboo, and it comes to the following conclusion: "Owing doubtless to the action of the medical profession in unanimously condemning the practice of employing arsenical colors in wall-papers—an action in which *The Lancet* took no small part—wall-papers loaded with arsenical pigment have apparently become a thing of the past, for among many specimens obtained by us from several respectable makers, those containing any arsenic at all contained it in almost imperceptible quantity, while others gave no response to a test which serves to detect the one fifty-thousandth part of a grain. Notwithstanding all this, it is necessary that a careful examination of wall-papers selected haphazard should from time to time be made in order that this satisfactory state of things may be maintained."

The American Health Resort Association.—This Association met at the Tremont House, Chicago, June 30th, with President T. C. Duncan in the chair. There were present representatives from numerous States, Canada, and Costa Rica. The President delivered an address on the work of the Association for the past year. In their investigations the claims of New Mexico as a resort for consumptives were fully sustained. The following are the titles of papers read by members of the Committee on Climate: "The Climates and Resorts of British America," "The Climate of the Northwest," "Climate of New Brunswick, and Its Relations to Consumption," "Consumption in Michigan," "The Climate of Napa Valley, California," "The Climates of California," "The Land of Sunshine," "The Climates of Nebraska" were presented in a report by C. W. Brown, of Superior, and "The Relation of Sun Spots and Magnetic Disturbance to Climatic Change." A strong resolution was adopted urging the medical profession and the public to give more attention to arresting the great mortality produced by phthisis pulmonalis. It was announced that a Congress of Climatologists would be held during the World's Fair in Chicago. The Association agreed to co operate with that Congress and meet next year in executive session only. Other papers presented were: "New England Climate and that of New Mexico," "Observations on California Climate," and "Climate Maxims." The Committee on Health Resorts presented the following reports: "The Value of the Lake Superior Region as a Resort for Consumptives in the First Stages of the Disease," "Texas as a Resort for Consumptives," "Experience at Resorts and with Climates," "Costa Rica as a Health Resort," "The Lake Superior as a Health Resort," "The Adirondack Region and Its Relative Humidity," and "The Claim of Honduras as a Health Resort." The following communications were presented by the Committee on Mineral Waters: "Mineral Waters, Their Analyses and Uses," and "Bacteria in Mineral and Potable Waters." There were presented reports on the Hot Springs of Las Vegas, N. M., Cartago, Costa Rica, and Ojo-Caliente, N. M., also on those of South Dakota, Salt Lake City, and Eureka, Ark. The Association was invited to send representatives to test their merits.

The Treasurer reported a balance of $100 on hand. The following were the officers elected for the year: *President*, T. C. Duncan, M.D., of Chicago; *1st Vice-President*, J. F. Danter, M.D., of Toronto, Ont.; *2d Vice-President*, I. N. Danforth, M.D., of Chicago; *3d Vice-President*, W. P. Roberts, M.D., of Boston, Mass.; *Treasurer*, T. S. Hoyne, M.D., of Chicago; *Recording Secretary*, W. A. Chatterton, M.D., of Chicago; *Corresponding Secretaries*, J. D. Hartley, M.D., of Chicago; W. S. Haines, M.D., of Chicago; W. W. Van Barry, M.D., of Philadelphia. The Association adjourned to meet during the session of the Congress on Climatology during the World's Fair next year.

Information concerning the Association may be obtained by addressing the Corresponding Secretary, Dr. J. D. Hartley, Chicago., Ill.

Therapeutic Application of Yawning.—In certain affections of the throat, such as acute pharyngitis, catarrh of the Eustachian tube with pain in the ear, a Swiss *confrère* says that he obtains excellent results from making the patients yawn several times a day. It produces, it seems, almost instantaneous relief; the symptoms rapidly subside, and the earache disappears. Frequently the affection is cut short by this novel treatment. Yawning produces, as everyone knows, a considerable distention of the muscles of the pharynx, constituting a kind of massage, and under this influence the cartilaginous portion of the Eustachian tube contracts, expelling into the pharynx the mucosities there collected. According to M. Naegéli, yawning is much more efficacious for affections of the tube than the methods of Valsalva or Politzer, and is more rational than the insufflation of air, which is often difficult to perform properly.

Another Case of Typhus Fever was detected among the passengers of the steamship Rugia, which arrived a few days ago from Hamburg.

Oxychinaseptol is the name of the latest antiseptic. Its use was demonstrated at the Eleventh Congress for Internal Medicine at Leipsic.

Epidermim is the name given to a new basis for ointments, composed of wax, water, glycerine, and an adhesive substance made of gum arabic and wax.

A Boy with a Bird's Head is being exhibited at the museums. The bird's head means that the skull has a peculiar shape, which Virchow calls nanocephalic.

For Urticaria, Quinquaud recommends alkalies internally and externally, a lotion of chloral 5.00, boric acid 45.00, and water 200.

Professor Koch has of late been incapacitated from work, and there is grave reason to fear that the condition of his health is such as to preclude the resumption of his duties for some time, at least.

The Epidemic in Paris is one of cholera nostras only.

A New Health-Resort.—Chicago has suddenly and to her own astonishment, no doubt, sprung up as one of the most remarkable health-resorts in the world. It is not so much a matter of ordinary observation as of statistics, which makes her so healthy. These statistics by the very latest census show that Chicago has a population of 1,500,000 inhabitants, or thereabouts. Her death-rate in July was a little over 400 a week; hence her mortality-rate for the year is about 14 per 1,000! Either the population is wrong or Chicago is the most salubrious large city in the world.

The American Therapeutist is the title of a new journal published in this city, and edited by Dr. John Aulde, of Philadelphia.

The Omaha Clinic publishes in one number three original articles, all of solid scientific value and worthy of a great medical centre. We propose to look out for Omaha as the coming metropolis of scientific medicine.

The Summer Season is at its height and the columns of this popular journal are open to cures for poison-ivy, summer diarrhœa, and preventives of mosquitoes.

A Cooling Drink.—A physician of this city takes antipyrin and water to keep down his temperature.

The Spiritualists are greatly pleased over the conversion to their ranks of the celebrated anthropologist, Professor Cæsare Lombroso. Nothing like it has happened since the testimony of Crookes to the reality of psychic force. It seems that Lombroso has gone no further than to affirm that certain table-tipping and like exhibitions, of prestidigitation were not "fakes," but real manifestations of occult force. This is surely going far enough, and we trust that the eminent savant is not going to lose his head over the silly humbug of old-time spiritualism.

A Seventh Case of Traumatic Tetanus Treated by the Tizzoni-Cattani Antitoxin.—Another case of pronounced tetanus, in which the treatment by the tetanus antitoxin was successfully applied, is reported by G. Casali (*Rif. Med.*, June 1, 1892). The details are as follows: The patient, a woman aged twenty-two, developed symptoms of the disease eight days after receiving an injury to her foot. The wound had quickly become inflamed, and the inguinal glands enlarged and painful; it had been in consequence washed with carbolic lotion and dressed antiseptically. The progress of the symptoms was fairly rapid, and when received into hospital, on the fourteenth day after the injury, the jaws were tightly closed, speech was indistinct, slow, and painful, there was marked "risus sardonicus," the muscles of the neck and back were stiff, and there was also some spasm of the injured limb. Tizzoni, on being summoned, confirmed the diagnosis, and cauterized the wound with silver nitrate, recommending the daily application thereto of the caustic in a one per cent. solution.

International Congress of Physiology.—The second meeting of the International Congress of Physiology, as already announced, will be held at Liége, on August 29th, 30th, and 31st.

Italian Congress of Laryngology.—The Italian Society of Laryngology will hold its first meeting in Rome about the middle of October. Among the subjects on the programme for discussion are the following: Phases, Nature, and the Treatment of Laryngeal Papillomata, to be introduced by Professor F. Massei; Diagnostic Importance in Ear Diseases of the Perception of Sounds by the Cranial and Aërial Paths, by Dr. Corradi; Diagnosis and Treatment of Diseases of the Sinuses Communicating with the Nasal Cavities, by Dr. Strazza. Communications have also been promised by Dr. Abate on the Diagnosis of Gouty Laryngitis; and by Dr. Fasano on the Co-existence of Syphilis and Tuberculosis of the Larynx, and on the Mercurial Treatment of Certain Nasal Scrofulides.

The Brains of Men and Women.—We find the following story, which, says the *British Medical Journal*, we venture to commend to the attention of Sir James Crichton-Browne, in a German paper. The late Professor L. Bischoff, the distinguished physiologist of Munich, was, it appears, fond of insisting on the intellectual inferiority of women to men, a fact which he attributed to the relative lightness of the female as compared with the male brain. As the result of laborious research, he had found that while the average weight of a man's brain is 1,350 grammes, a woman's only weighs 1,250 grammes. The fair sex must have felt itself amply avenged when, on the ungallant professor's death, his brain was found to weigh only 1,245 grammes. The ladies will probably say that this is only what might have been expected, and there is a poetical justice about the *dénouement* which makes one wish that the story may be true. The moral of the affair seems to be that men of science who deny the intellectual equality of the sexes on the score of relative weight of brains, should leave strict injunctions that their own brains are not to be examined after their death.

The Apothecary's Oath.—A correspondent of *The Medical News* writes: "While reading Boas's "History of Medicine," I found the following oath, as taken by the apothecaries of the thirteenth century: 'To honor, esteem, and serve the doctors of medicine, . . . to speak no evil, . . . and to do everything which may contribute to the honor, reputation, embellishment, and majesty of medicine.' Is there a nineteenth-century apothecary that would show his allegiance to and dependence upon the medical profession as did these men of old? Where has progress shown itself along this line? What cares the druggist for the doctor to-day when he has the quack to back him?"

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, held in New York, June 22, 23, and 24, 1892.

C. L. DANA, M.D., PRESIDENT, IN THE CHAIR.

A Neurological Outlook was the title of the President's address (see p. 126).

Researches upon the Etiology of Idiopathic Epilepsy.—DR. C. A. HERTER, of New York, read a paper on this subject. The speaker had, during the past winter, undertaken to study the relation of uric acid excretion to the epileptic paroxysm, a line of inquiry brought to notice by recent publications of Haig, an English writer, who believed that the *grand mal* seizure was determined by an excessive accumulation of uric acid in the blood. The speaker's results were not confirmatory of the view by Haig. Certain observations, however, of another kind had suggested the possibility of a causal relationship, in some cases, between putrefactive processes in the intestine and epileptic seizures. The possibility of this was suggested on considering that in cases of epilepsy the symptoms of disordered digestion were associated with an unusual frequency of the seizures. Certain substances in the urine, namely, the ethereal sulphates, had been shown to be derived from putrefaction in the intestine, and the extent to which such putrefaction occurred might be inferred from the quantity of these substances in the urine. These substances had been studied in thirty-one different cases of epilepsy, most of the cases being unquestionably idiopathic in nature, according to the generally accepted meaning of the term. In the majority of these cases the uric acid excretion also had been studied. Of the thirty-one cases of epilepsy, *grand mal* seizures were the distinctive features in twenty nine. In the remaining cases there were very frequent *petit mal* seizures. In the cases of *grand mal* the excretion of uric acid before the seizure had only in rare instances varied from the limits of health, whereas, in general, it might be said that the urine passed after a seizure was apt to have a higher uric acid ratio than the urine before or about the time of the seizure. This was to be regarded as a consequence of conditions which had determined the seizures, or possibly to the seizures themselves, but could not reasonably be construed as the cause of seizures. In the *petit mal* cases a continuously high uric acid excretion had been observed and appeared in some way to be related to the cause of the seizures. It was found in two cases of this type that when the excretion of uric acid was reduced, the seizures were greatly reduced in frequency. As to intestinal putrefaction in epilepsy, of the twenty-nine cases of *grand mal*, twenty-one of them showed unmistakable evidence of excessive intestinal putrefaction. Furthermore, a large proportion of the cases in which the observations were of such a character as to render a comparison possible, showed at least a general correspondence between the seizures and the degree of intestinal putrefaction, as gauged by the analysis of the urine. As regarded the possible dependence of these results upon any peculiarity in the diet of the patients, it might be said that no peculiarity existed. Their non-dependence upon the influence of the bromides was less easy of demonstration, yet, for reasons which seemed to be satisfactory, the speaker thought it highly improbable that the bromides were responsible for the evidences of putrefaction.

DR. B. SACHS thought, that despite the excellent work done by the reader of the paper, the mystery which had surrounded the etiology of idiopathic epilepsy still remained.

DR. E. D. FISHER had seen some of the cases referred to and thought that the clinical facts tallied with the conclusions so far deduced by the author of the paper.

DR. F. X. DERCUM asked if there were any facts which would go to prove that the ethereal sulphates were really irritative in their action.

DR. HERTER replied that as yet no experiments had been made with a view to determining this point, but the evidence suggested a relationship of the kind mentioned, though it was not as yet proven.

DR. WHARTON SINKLER cited, as illustrative of the action of putrefactive changes in producing epileptic attacks, the case of a patient who as a rule had a seizure every two or three months, but who had found that such attacks could be frequently warded off by active purgation.

DR. RIGGS said that in the use of antiseptic agents he had found the addition of naphthol and charcoal to the salicylate and sulphate of bismuth valuable in reducing the putrefactive changes of a nitrogenous diet.

DR. HOBSON thought it was a question whether the presence of ethereal sulphates might be regarded as a cause or effect of the epileptic condition.

DR. H. A. TOMLINSON emphasized the fact that keeping the bowels open and taking a proper amount of exercise insured to the epileptic fewer convulsions and a less uncomfortable existence.

DR. HERTER said that these substances acted not as a primary cause, but as irritants upon a predisposition. It was important to distinguish between the relation of uric acid excretion and the excretion of the ethereal sulphates. It had been determined by observation that the proportion of uric acid was largely increased after an epileptic seizure, reaching the maximum one or two days after the attacks. The ethereal sulphates were, on the contrary, increased at the time or immediately before.

Sleep Movements of Epilepsy.—DR. J. W. PUTNAM, of Buffalo, read a paper with this title. When there was no history of cranial injury in a case of epilepsy, we often got a history of the character of the attacks, and upon this history of the aura and the muscles first convulsed we were obliged to rely for our localization. Owing to the nature of the disease, dependence had to be placed upon the observation of others in regard to preliminary movements, and it was often difficult to obtain clear and positive statements concerning these. Last fall the speaker had a patient who was at that time having a convulsion almost every evening, and while waiting to observe an attack he had noticed a peculiar movement of the left arm, which was different from the ordinary purposeless movements of restlesss sleep. The speaker thought that a series of observations of epileptics during sleep might show movements which might be of localizing value. Hughlings Jackson had assumed that there were three levels in the motor nervous system: the highest, chiefly motor, was the frontal lobes; the middle level was composed of the portion which we understood as the motor region, comprising the ascending frontal and parietal convolutions and the corpus striatum; the lowest level consisted of the cornua of the cord, Clark's column, and Stelling's nucleus. Starting with this theory the speaker ventured the following explanation: When the patient was in a profound sleep, all these levels were in a state of functional rest, and we had a quiet sleep undisturbed by movements, as no stimulus was transmitted to the muscles. In a less profound sleep he had assumed the highest level to be at rest and no longer exerting an inhibiting control over the middle level. This in a healthy person would show itself by general restlessness. In an epileptic in whose motor region there was an irritated area of greater excitability than normal it was assumed that it was less profoundly asleep than other areas. Hence, in such conditions we might have pronounced and definite movements occurring during sleep and limited to the limb controlled by the irritated area.

DR. J. J. PUTNAM thought that in epilepsy, as a rule, the lesion consisted of diffuse sclerotic changes acting diffusely, as did poisons. The focalized expression of these changes indicated that certain portions of the brain were, or had become, relatively more influenced by the

morbid changes. Operative procedures were not likely to succeed if this theory was correct. He should be disinclined to operate for localized movements occurring during sleep.

Dr. Sachs thought that sleep movements might point to the fact that the centre governing the part moved in sleep would be more irritable than normal. He was reluctant to attach too much value to the sleep movements as a symptom.

Dr. J. W. Putnam did not think it would be justifiable to have operations undertaken upon observations of the sleep movements alone. Still he thought they indicated the seat of irritation, and hence there was added one more strand to the rope of evidence.

The Seat of Absinthe Epilepsy.—Dr. Isaac Ott, of Easton, read a paper on this subject. Anatomy had, as yet, been of little service in revealing the seat of epilepsy, but much more had been accomplished by physiology in the elucidation of convulsive phenomena. The speaker reviewed the various experiments that had been made from time to time in localizing convulsive movement, but dwelt especially upon the absinthe tests. One observer had found that after injection into the jugular vein of two drops of essence of absinthe, there followed these conditions: The facial muscles began with a single clonic spasm passing into a state of tremulous tonic spasm. This order of convulsion passed rapidly down the body, until the tonic spasm in the limbs was extremely marked. After a short period, tonic spasms gave way to a long series of clonic twitches. Accompanying these convulsive phenomena there was a profuse salivation and sometimes escape of urine, while in cases in which narcosis had not been employed, unconsciousness and coma were early symptoms. The effect upon the cord was also tested by means of the galvanometer and the electrometer. The results showed that the employment of absinthe gave maximal electromotive effects in the sciatic nerve through the overwhelming discharge of the highest cortical centres. It was also observed that absinthe caused an additional electric excitation of the centres, producing more energy. A number of facts proved that the seat of origin of tonic and clonic movements in epilepsy was in the cortex, and their expression took place mainly by means of ganglia seated in the pons. That clonic convulsions could be observed even after removal of the brain in front of the pons was proven by the author in one case, in which the injection of essence of absinthe produced violent clonic spasms. The word cortico-pontal might express the origin of convulsive epilepsy due to absinthe.

Separate Provision for Epileptics, both Public and Private.—Dr. Henry R. Stedman, of Boston, entered a plea for the exclusive care of epileptics in special establishments, on the colony plan, throughout the country. The amelioration, by proper medical supervision in surroundings, where their lives could be regulated, their capabilities in the way of employment developed, seemed not to attract the attention it ought. That this was practicable, the colonies for epileptics in other countries, particularly in Germany, had rendered an assured fact. The speaker gave a short account, illustrated by charts and views, of the famous epileptic colonies at Bielefeld, in Germany, which he had recently visited. He closed his remarks with the hope that some step might be taken in this country to establish like institutions.

Dr. Bullard said that in Massachusetts steps had already been taken to further the establishment of suitable special institutions for the care of epileptics. A bill has been prepared by a special committee and presented to the proper quarter. It was hoped and believed that next year this bill would be passed and the money forthcoming to secure the end in view.

Dr. Frederick Peterson urged the necessity for energetic support of the measures already taken in New York State, and said that if the hopes of those interested were realized, a very large number of epileptics would have opportunity for instruction and of leading useful lives.

Dr Fisher said he hoped the movement would meet with every success. He did not know a more helpless, hopeless set of human beings than these epileptics, fed on bromides and without occupation.

Dr. William M. Leszynsky asked if it was intended to include the care of the cases of chronic epileptic insanity. He should think these formed an undesirable class to colonize with the ordinary epileptics.

Dr. Tomlinson said there was no more unsatisfactory class of patients in institutions for the insane than the epileptics. Not one of these institutions was suitably equipped to care for them. If they were associated with the violent and demented, their lives were rendered still more uncomfortable.

Dr. Sachs was in favor of provision by the State for these patients, but thought that much must be done by private endeavor. Many of the younger epileptics among the well-to-do had no opportunity for proper education. It had seemed to the speaker that for these there should be provided private institutions, where it would be made an object to give distinct educational advantages.

The President said he had made some investigations in the matter. He did not believe that there should be any State provision for epileptics, at least not at present. There were now an enormous number of defective institutions under political influence. If there were added sixteen thousand epileptics to the fifteen thousand insane, the condition of the former class would be by no means benefited. While the institutions for which Dr. Stedman pleaded were undoubtedly needed, effort should be made toward interesting private citizens in their support.

Dr. Stedman said that it would, of course, not be wise to associate the violent cases of epilepsy with those of the milder class. Buildings could, however, be provided on the colony where the severe cases could be cared for. He agreed as to the desirability of charitable work in the scheme, but it seemed difficult to effect the desired end in this way from the very great lack of interest in this unfortunate class, and it was only by State care that there was hope of benefiting them.

The President thought that a direct opinion on the subject by the Association might bear weight with the Legislature, and hoped that some such expression would be formulated. The following resolution was, on motion of Dr. Stedman, then adopted: "That it is the unanimous sense of the American Neurological Association that the proper care of the epileptic class, so long delayed, be urged upon the public, upon State authorities, and especially upon all interested in the care of the sick and defective poor, whereby they may be relieved from asylums and almshouses, and may receive the required care in such separate establishments as their deplorable situations demand."

A New Symptom Indicating Combined Cerebellar and Spinal Inco-ordination.—Dr. E. C. Spitzka, of New York, reported the case of a child whose attitude and appearance were characteristic of that form of pseudo-hypertrophic paralysis in which the atrophy of the arms markedly ante-dated wasting in the lower extremities. Whether dressed or undressed, under examination and observation or not, the patient had a habit, with his right hand, thumb and fingers flexed, the fingers but slightly so, of making a sudden motion toward the nose, while at the same time there was a straightening out in his attitude as if all the muscles involved in maintaining the erect posture were associated in the act. A peculiar expression would cross his face, the head and eyes being turned toward the approaching fingers. The child had also certain imperative conceptions, such as the fear of going under a certain tree, a terror of a Newfoundland dog at the later hours of the day, which at other times he showed a great affection for. He had also a fear of the stairs, and even on the level floor of the house he had an impression as of a yawning precipice. The mother had informed the speaker that there

were three members of her husband's family in insane asylums. The child had progressed as these cases usually did, had developed a more marked grade of imperative conceptions and morbid fears, and a slight grade of imbecility.

A Further Contribution to the Pathology of Arrested Cerebral Development.—Dr. B. Sachs, of New York, read a paper with this title. The patient who was the subject of the paper was a sister of a child whose brain the speaker had reported upon five years ago. The history of the case was as follows: The child when first seen was thirteen months old. It was born at full term, a perfectly healthy infant, was nursed at the breast, and had appeared to be developing finely until the age of eighteen months; from that time there had been steady retrogression. Close examination showed that the child could not hold up its head, nor could it sit up unless supported; it had no perception of light, and the pupillary light reflex was entirely gone. There was slight sense of hearing, but it could not distinguish between sounds. There was some spastic condition of the upper and lower extremities, but no spontaneous movements of any sort, the child sitting listlessly on the nurse's lap. The knee-jerks on both sides were distinctly exaggerated, no ankle clonus was obtainable, the plantar reflexes were increased. The condition had grown steadily worse, and the child had died of extreme marasmus at the age of twenty months. A week before death there had been considerable fever and several convulsive seizures, but these were the only ones that had occurred during the entire course of the disease. An autopsy was performed twenty-two hours after death. There was no evidence of latent specific disease. The skull was symmetrical, of good size, but unusually thin; the fontanelles were closed, but still transparent. The dura was adherent to the skull, so that the brain had to be removed with the calvarium. The brain was firm to the touch, almost as hard as a brain that had been in Müller's fluid for some weeks. The pia could be easily detached, and the cortex, though pale, presented no unusual appearances. The cord presented no abnormal conditions. Very careful microscopic studies were made of sections of the ganglia, pons, medulla, and cord. The chief changes, and very marked ones, were found in the cortex, in all of its regions to an equal degree. In all of the sections examined not a single normal pyramidal cell could be discovered. The cell-bodies were altered either in shape or in general appearance; the cell nuclei and the nucleoli were distinct enough, but were surrounded by an altered cell-body which did not properly take the ordinary stains. The neuroglia cells appeared somewhat increased and the tissue rather dense. The blood-vessels were present in at least the usual proportion, most of them being filled with blood, but there was no sign of any active inflammatory condition. Comparing the results of examination in this case with the facts published a few years ago, that the arrest of cerebral development was practically an arrest of cortical development, a true *agenesis corticalis*, was made out, but by what immediate force it was brought about it was difficult to say. In the case of the other child whose sister this one was, the history of traumatism during pregnancy was looked upon as a possible cause, but in the present instance that factor was wanting. From the results of the two autopsies it might be claimed that the chief morbid changes underlying that form of idiocy which was associated with blindness, and which led to a prompt and fatal termination, was to be found in the cells of the cortex. This case could hardly be dignified as a distinct type of disease, but it represented the most pronounced form of idiocy and of arrested cerebral development.

Report upon the Surgical Treatment of Epilepsy.—Dr. Sachs also gave a record of his joint experiences with Professor A. G. Gerster in the surgical treatment of epilepsy. The cases operated upon were selected with considerable care. They were either of distinctly traumatic origin, or such in which a strictly localized convulsion pointed to a limited focus of disease. Cases of general epilepsy of non-traumatic origin were not subjected to operation. In regard to the determination of the brain areas to be operated upon, it was the custom to map out upon the skull with the greatest care, in advance of the operation, the exact site of the various divisions of the motor areas. The speaker was now of the opinion that in most cases this was quite unnecessary, and that the application of the faradic current to the dura would help to localize centres much more accurately than any of the customary rules. The first and most notable result of the operations, as recorded by these observers, was that they could not claim a single decided cure. In several of the cases there had been a marked diminution of the attacks immediately after the operation; in some the improvement had lasted a few months, but in every single case the attacks recurred after a lapse of several months, or even less. If we sought for some special reason why operative procedure had accomplished so little, it was to be found in the fact that they came under notice after the epilepsy had been established for many years. It was now generally conceded that, though a focus of disease was the actual cause of the epilepsy, this epilepsy did not manifest itself as a rule until widespread changes had appeared throughout the entire brain. The time that elapsed between the infliction of the initial lesion and the development of these secondary changes corresponded quite accurately with the period of time between the traumatic injury, or the initial disease, and the development of epilepsy. The excision of the cortical tissue after the establishment of epilepsy seemed to be of questionable merit. The only hope from surgery was in the prompt interference, in all cases of traumatic injury to the skull, to remove the focus of disease before secondary changes had been set up.

Dr. Mills had reported two cases at certain periods after operation, and in one the result was absolutely valueless. In the other the patient, up to the time the speaker had last heard of him, ten years after the operation, had had no return, but even before the operation the patient had had but few attacks, and the disease had existed only a very few months.

Dr. J. J. Putnam thought that while something ought to be done, in early infancy, to remove diseased portions of the brain, there was evidence wanting that epilepsy would be thereby prevented.

Dr. P. C. Knapp had not seen any beneficial results from the treatment. From local injury there supervened a localized epilepsy, due however to changes in the brain, and he believed that in many of these cases, by the time the first convulsion appeared, there were already extensive changes in the brain itself.

Dr. Sachs said that in the event of any difficulties being met with in obtaining local muscular contractions upon faradization of the dura, there must be some mistake in the technique. It was a fact that through the dura there could be produced a series of single contractions of just these parts, the centre of which it was desired to excise. This could be done upon man just as well as upon the brain of the monkey. Dr. Knapp had spoken of localized convulsion due to the general changes in the brain. The speaker did not entirely agree with this view, but thought it more likely to be localized convulsion due to localized lesion. It was a question whether operation promised much, even in traumatic cases, unless undertaken in the earliest possible stages.

Some Contributions to the Muscular Sense.—Dr. G. J. Preston, of Baltimore, read an interesting paper with this title, which he summed up in the following conclusions: 1. The posture sense was composed of afferent impulses derived from muscles, tendons, articulations and their coverings, and bones. 2. It was independent of, and separable from, general tactile sensibility, and possibly could be distinguished from the other members of its class, as the pressure sense, for example. 3. The

course of these impulses through the cord was almost certainly by means of the posterior columns. 4. They probably passed into the corpus restiforme and cerebellum. 5. In all probability they passed through the anterior portion of the posterior third of the posterior limb of the internal capsule, occupying an intermediate position between the motor and sensory fibres in this region. 6. Without positive data on either side, it would seem most probable that the centre for the posture sense was located in one of the cell-layers of the motor cortex.

The Extent of the Visual Area of the Cortex in Man.—Dr. H. H. Donaldson, of Worcester, made some remarks on this subject. He spoke of the post-mortem findings in the case of Laura Bridgman, who had lost the power of vision in the left eye at the age of twelve, and said that a study of cases in which the sense organs had been lost in early life, as also in animals where they had been experimentally removed, might materially aid in marking the sensory areas.

The Criminal Brain Illustrated by the Brain of a Murderer.—Dr. Donaldson also read a paper on this subject. He said that a specimen obtained from Dr. Van Gieson had been examined, with a view to determine whether it corresponded with Benedict's notion, that confluent fissures were characteristic of criminal brains. Examinations of this particular brain, that of a murderer of undoubtedly criminal characteristics, showed that it did not correspond with the type as described by Benedict. Giacommni had determined by comparison that there were more confluences in normal brains than in those of criminals. If increased fissuration was a criminal characteristic, this, other things being equal, implied an increase of gray matter, and, therefore, low-type brains might be said to have proportionately a larger amount of gray matter. Undoubtedly, the criminal brain could be picked out of a mixed lot, but only by virtue of general characteristics, and there could be no certainty that all criminal brains could be thus selected. The characteristics of degeneracy, such as were to be found about the rest of the body, were not as yet sufficiently marked to be expressed in a systematic manner.

Dr. Collins said that, from a somewhat limited experience at three or four autopsies on murderers, he was not prepared to say that there was a criminal brain, although there were often found fissural and gyral peculiarities which merited study and observation. In the autopsy on a murderer who had lost his life in attempting to take that of a New York financier, the speaker had found really remarkable structural changes, and whether these were the result of retrograde changes during life of the murderer, or an inherent structural absence from the beginning, he could not say. The fissure of Rolando was very shallow, the gray matter thinner than normal, the ascending parietal convolution was small, and the entire left hemisphere gave an idea of changes from the normal in conformation. Further careful comparisons between the brains of the known criminal class with those of a known high order were necessary before any valuable conclusions could be drawn.

Dr. Charles K. Mills believed that there were many misconceptions on the part of those who criticised the observers who had reported aberrations and irregularities in the brains of criminals. No one believed that all criminals presented a brain anatomy that would enable them to be ranged under a special type. Criminals belonged to very different classes. A criminal type of brain could be expected from those who were victims of a bad heredity or very early arrest. Paranoiacs, criminals, idiots, imbeciles, those generally who were victims of arrested or abortive development would probably present brain abnormalities even of a gross kind. The brain shown by Dr. Donaldson exhibited what seemed to him to be evidences of aberration, particularly in the parieto-occipital region. The subject was one, however, that could only be settled by careful and prolonged investigation.

Dr. Knapp had nothing to say as to the anatomical conditions, but he wished to support Dr. Mills's view as to the distinction between criminals. It was as vague to speak of a criminal brain as it would be to speak of an insane brain, classing together indiscriminately mania, melancholia, paranoia, and general paralysis.

Description of a Chinese Brain.—Dr. F. X. Dercum, of Philadelphia, gave the record of such an examination. In all of the brains of Chinese so far examined by the speaker, an unusual tendency to transverse or perpendicular fissuration was present. There was also unusual sinuosity of the fissures. Of the gross peculiarities, there was a marked obliquity or eversion of the basal surface of the frontal lobe. In both of the previously described specimens of the writer's complexity was given to the frontal lobes by the appearance of well-marked medifrontal elements. In the present specimen an added frontal fissure was present on the left lobe, but it was comparatively short, and in the right lobe traces of it only were found. In both of the former specimens the cuneus and the occipital lobe were noted as rather small; this held good in regard to the present case. In conclusion, these brains, owing probably to the unusual sinuosity of some of the fissures, together with the excessive transverse fissuration, had a physiognomy, as it were, of their own. They certainly, in general appearance, looked different from the average white brain and also very different from the brain of the negro.

The Association of Hysterical Trembling and Anorexia Nervosa.—Dr. James Hendrie Lloyd, of Philadelphia, read a paper on this subject. He reported the case of a young woman who had been first observed at a remote farm-house in Pennsylvania. She had then been ill for two years. She was suffering with a peculiar rhythmic, constant tremor, which was, however, not paralysis agitans. The tremor occurred in waves of exacerbation and opisthotonic spasms every minute or so. The patient had hysterogenic zones, pressure over which caused the spasm. She had also the condition described by Gull as anorexia nervosa. By a mistake a large dose of ordinary saltpetre had been given instead of sulphate of magnesia. While no harm had directly resulted from this error, the mental disturbance had been such that regurgitation of food had set in, and this had become the most pronounced complication in the case. The patient was found lying upon her side with cloths under her chin to catch the regurgitated material. She was emaciated to the last degree. There was no atrophy, but simply inanition. This condition was followed by true hysterical retention of urine, lasting sometimes for two days. After the patient had been removed to an hospital the tremor had greatly subsided and the regurgitation of food had entirely stopped.

Dr. Riggs cited the case of a woman under his care believed to be suffering from hysterical tremor. It was peculiar in that the attack came on only during the morning hours. He was unable to find any of the stigmata commonly present. There was persistent nausea and continuous headache. Under the usual therapeutic measures the patient had steadily improved.

Dr. Weber said that these patients did not really swallow, at least the food did not pass into the stomach. If food was passed into the stomach through a tube, they did not vomit.

Dr. Preston said it was necessary to distinguish between hysterical tremor and the nervous trembling of Charcot. In a case of his, of hysterical anorexia with nervous tremblings at intervals, the patient had lost fifty per cent. of body weight.

Dr. Mills thought it important to determine that the tremor or abnormal movements were not purely hysterical, or associated with melancholia or some organic disturbance. A diagnosis of the hysterical character of the tremor was to be made chiefly from the association of other hysterical conditions. As to the prognosis, many of such cases would outlast the medical observers.

Dr. Sachs said that as pronounced cases of hysterical anorexia, with trembling, were to be met with here as in Paris. He cited the case of a young woman who had refused absolutely to take food on the plea that she could not swallow. Efforts were made to administer food by force, but she would keep a large mass in her gullet and then go into a corner of the room and eject it. When fed she would gag and regurgitate a little, but it was believed that it was not true vomiting. The male hysterical patients were much more difficult to handle than the female. He believed that the majority of these patients did swallow, and the best proof that they were not without food lay in the fact that they increased in weight in spite of the assertion that no food was taken. He believed that few of these cases of hysterical anorexia would be found to resist cold water, applied under considerable pressure.

Folie à Deux, with Remarks on Similar Types of Insanity.—Dr. C. K. Mills presented notes on two cases of this disease. The two patients were sisters, the eldest thirty-two years of age, the other less than two years younger. The father was a hard-drinking, quarrelsome man. The first patient had been deranged for three or four years. She had complained of strange feelings, as of something growing in her abdomen, of sickness of the stomach, bloody passages, chills, and other unpleasant sensations. She had been troubled for a long time with strange voices. She was tormented by people both at her work and at home, and was made to say very ridiculous things. She apparently had hallucinations of several senses. A stench of blood came up through her throat; at times she was grasped by a hand. Men would appear before her, and sometimes they would get on their knees and solicit her. She was full of sexual delusions with reference to men and their designs upon her. The heads of men would appear before her at her work. When she did not see them, sometimes she would feel them or hear them; often she heard their voices talking with her after midnight, saying all sorts of filthy things.

The other patient's mental disturbance had come on a few weeks after that of her sister. Apparently the delusions of the first had, to some extent, been imposed upon or communicated to the second. Besides having various physical symptoms, the second patient, who seemed to be weaker both mentally and physically than the other, told the most filthy stories. She said that she knew who the men were that were abusing her. These patients had evidently become a nuisance both at their home and in the neighborhood. They appeared to believe firmly in what they said, and yet, at times, to appreciate that something was wrong with their heads. They eventually went quietly and without resistance to a hospital for the insane, thinking, apparently, that they might be able to get their troubles straightened after they got there. They presented, as is not unusual, a blending of the characteristics of the three forms of folie à deux, that is of the imposed insanity, the simultaneous insanity, and the communicated insanity. The influence of heredity was decided; the delusions were persecutory.

Rapidly Fatal Motor and Sensory Paralysis, with Acute Myelitis of the Dorsal Cord.—Dr. Mills reported a case of this nature. The patient, a man thirty-seven years of age, with an uncertain specific history, six months before coming under observation had had a large carbuncle between the shoulders. For months he had shown some tendency to drag his feet. For two weeks he had had pain and soreness nearly in the line of the right nipple, which extended later into the armpits and down the inner side of the arm. Four days before he was first seen he had developed a severe pain across the loins. The next day he was barely able to walk, and in thirty-six hours he could not stand. Twenty-four hours later he was completely paralyzed as to motion in both lower extremities, and showed also total loss of sensation as high as the nipples. He had incontinence of urine and fæces. Knee jerks, muscle-jerks, and cutaneous reflexes were abolished. This extreme paralysis was fully developed three days after the first symptom of motor loss became marked. His temperature rose rapidly to 104° and 105° F., with corresponding increase of pulse and respiration. He died one week after coming under observation. At the autopsy the vessels of the spinal pia were markedly distended with blood. On section the periphery of the cervical cord was of good consistence, but the centre was much softened. As the sections were made lower down the transverse area of the softening increased, until in the dorsal region only a shell of solid tissue surrounded a creamy mass. The softening grew less again in the lumbar region. Below the right groin was a swelling which contained broken-down glands and pus. Other organs and parts were found to be normal. Microscopical examination showed, in the dorsal region, the nervous tissue almost entirely destroyed. The blood-vessels were distended, and there were many scattered hemorrhages. Hemorrhages were also present in the pia and in some of the peripheral nerve-roots. The upper part of the cervical region was very little affected, and the lumbar much less than the dorsal. The case was unquestionably one of rapidly spreading acute myelitis.

Exploratory Trephining and Ligation of the Vertebral Artery.—Dr. J. B. Deaver and Dr. Mills reported a case which they regarded as of unusual character, and probably unique. The patient was a boy aged eleven, who had, in December, 1889, commenced to complain of pain in the head and some stiffness of the neck. Other symptoms, which had developed slowly, were failing sight, spells of nausea, occasional attacks of violence or excitement, strabismus, staggering in walking (a little more to the left than to the right), a feeling of dizziness described as "going over," and shortness of breath. Before the operation double optic neuritis in an advanced stage was present. Hearing and taste were not impaired, there was no motor paralysis, nor was there disturbance of common sensibility. No nystagmus Examination showed a pulsating tumor in the occipital region, slightly protruding through a small opening in the skull, to the left of the occipital protuberance. A distinct thrill seemed to be present. Three scars were noted on the posterior aspect of the head, one just above and to the right of the opening. The opening in the skull was enlarged so as to examine the supposed aneurism which appeared to be in the line of the lateral sinus, but when this was done the character of the swelling was too uncertain to warrant them to go farther. An exploring needle was introduced, the withdrawal of which caused bleeding which required long pressure to arrest. Later the left vertebral artery was ligated, but with no beneficial results. After the operation the pupil on the side corresponding to the cicatrix was contracted. The patient slowly grew weaker and died several months after the operation. Autopsy revealed a gelatinous mass which had occupied much of the fourth vertricle, reaching from or into the middle lobe of the cerebellum and both cerebellar hemispheres. The ventricles of the brain and their horns were enormously dilated, and at several places at the base rupture had almost taken place into the cranial cavity. When the spinal cord was severed from the oblongata, the central spinal canal was found to be one-sixth of an inch in diameter, and from it much fluid escaped. The chief points of interest were the reference to the diagnosis of aneurism, the mechanism of the process by which the opening in the skull resulted, and the production of the hydrocephalus and hydrorachis.

A Case of Congenital Huntington's Chorea.—Dr. L. C. Gray, of New York, presented a man suffering from alleged hereditary Huntington's chorea. The disease had manifested itself in the same family during many generations. The movements and progressive muscular tremors appeared in this case when the patient had reached the age of forty-five. The man belonged to some branch of the Stamford County family. The speaker did not con-

sider the swaying and dancing movements in this case those of chorea.

Dr. Gray then showed a case in a child which he considered was one of congenital Huntington's chorea. There had been no similar trouble in other members of the child's family, and the general history was negative. The choreic movements had been noticed immediately after birth. The infant was a seven months' child. This disease showed itself generally between the ages of thirty and fifty, and this was the youngest case known to the speaker.

Dr. J. H. Lloyd thought that the so-called Huntington's chorea, which was clinically very similar to ordinary chorea, was dependent upon a different pathology. He had observed in Philadelphia a woman of eighty with senile chorea There was always an associated mental failure in those forms of adult chorea.

Dr. Sinkler said that a Dr. Stevens, of South Carolina, had reported a family in which there had been cases of chorea for several generations. The same observer had reported two cases in young adults, in whom the choreic movements had commenced in infancy, before the end of the first year. The case before them was certainly different from ordinary chorea, and was much more like spinal disease.

Dr. Collins had observed the case of a child of eleven in whom the movements, which dated from birth, were more characteristic than in Dr. Gray's case. In the patient before them the lesion was probably one of the medullary areas, and the choreic movements were associated with lack of development high up in these areas.

The President presented a case of hereditary chorea in a man, a native of Scotland, in whose family the disease had appeared through four or five generations. The speaker presented this case to show the effect of trephining. The temporary relief afforded by the operation in general paresis had suggested the probability of some such result in this case.

Dr Gray said that autopsies would not substantiate Dr. Sinkler's views as to the spinal origin of this disease. There were only one or two cases in which spinal degeneration had been noticed, and the lesions had been usually in the cerebrum, in the motor tract.

Traumatic Nervous Affections.—Dr. Philip Coombs Knapp, of Boston, read a paper on this subject. He held that there were various distinct affections of the nervous system due to injury, and that no one term such as traumatic neurosis could be applicable to all. The paper he said was an attempt at classification based on ninety cases. Pain in the back was present in fifty-six cases, trouble in the back was the chief disturbance. In the rest it was only a complication.

Five cases were due to direct injury to the cord, producing paraplegia. In four cases there were symptoms of insidious onset referable to the cord, paresis, vesicle disturbances, and slight spastic condition. Here it was thought that the changes were chiefly in the lateral columns. Thirteen cases were regarded as of more distinctly cerebral origin. Here the injury had been to the head, and the prominent symptoms were headache, vertigo, and loss of mental power. Other symptoms sometimes indicated a focal lesion, hemorrhage, fracture, or meningitis. Twelve cases were believed to have an organic basis, a diffuse sclerosis of the cerebral nervous system. Four of these had terminated fatally. Four others were thought to belong to this class, but they were classed as doubtful. The symptoms were pain in the head and back, loss of mental power, insomnia, muscular weakness, anæsthesia usually of general distribution and most marked in the legs, tremor, disturbances of micturition, and palpitation. In these cases the psychical element had little to do in the causation. In the functional conditions the psychical element was much more important. Twenty-six cases were classed as neurasthenic. In all cases of "spinal irritation," headache, insomnia, digestion disturbance, incapacity for protracted physical and mental effort, nervousness, hypochondria, melancholia, morning fatigue, etc., were prominent symptoms. A rapid pulse and an exaggerated knee-jerk were considered of some importance. Seventeen cases were classified as hysteria, and presented some of the symptoms, notably hemi-anæsthesia, on which the French lay so much stress. Most of them also presented symptoms of neurasthenia. Pure hysteria was very rare. Limitation of the visual field was common in hysteria, but was rare in other affections. Both this symptom and hemi-anæsthesia were of importance, but they were met with only in a small percentage of the cases. Successful simulation was believed to be extremely rare. The prognosis depended upon the form of disease.

Dr. J. J. Putnam thought that neurologists had a peculiar responsibility in regard to this subject, and it was his earnest desire that the question of prognosis should be tested in every way, and as large a series of cases as possible should be accumulated and classified, as to age, sex, and temperament. Much more light was needed before a judgment that was fair could be given. No expert had any excuse for not knowing practically all that had been discovered on the subject. There had been a serious accident at Roslindale, and the speaker had had special opportunities of observing the worst cases among those injured. Only a very small number of these would admit that they had entirely recovered. In the experience of the speaker the effect of treatment was good after a certain time in removing certain factors in the cases. He believed simulation to be of rare occurrence. Hypnotism, while likely to do harm if indiscreetly employed, was one of the edge tools the proper use of which would give good results.

Dr. Dercum thought that sufficient attention had not been paid to the existence of a certain group of motor symptoms in some of these cases. There was not only weakness amounting to absolute paralysis, but a condition of motor erethism, fibrillary tremors, spasms of the back muscles, and so forth.

The subject was further discussed by Drs. Tomlinson, Jones, Brill, and Mills.

Treatment of Syphilitic Nervous Affections.—Dr. E. C. Spitzka, of New York, made a few general remarks on this subject. Authorities on myelitis and other organic spinal disorders had not recognized the clinical difference between gummatous and acute vascular syphilitic affections of the spinal cord on the one hand, and tabes dorsalis on the other. There were two special diseases of the nervous centres which had more or less connection with syphilis. For instance, in locomotor ataxia, we know how frequently a history of syphilis occurs in the etiology of this disease; but the connection is not of the same kind as is found between the secondary and primary lesions of syphilis. The speaker believed in the existence of dementia, due to syphilis, which was not true paretic dementia. Emp rically, he stated that the more rapidly a central nervous syphilitic lesion was developed, the more rapidly fatal or radically curable it was. The more slowly developed disorders attributable to constitutional syphilis are amenable to carefully instituted antisyphilitic treatment in their early phases. If an established sclerosis be affected at all by the iodides or mercury, it is no more so than in non-syphilitic cases. Finally, the later the outbreak of nervous sequelæ, the less useful will the iodides be, and the more useful mercurial preparations and the associated baths. An interrupted plan of treatment, covering a long period of time, is more applicable to late cases than the energetic single course.

The Toxic Origin of Insanity.—Dr. Theodore H. Kellogg, of Flushing, read a paper with this title. Whenever a poison entered the human system, and through its presence directly or indirectly caused prolonged derangement of the mental functions, it was but reasonable to call the insanity toxic, and to regard the deleterious substance

as the exciting cause of the disease. It was true of this exciting cause, as of all others, that it would act only in cases having a native instability of nervous centre. The toxic agent might be vegetable, animal, or mineral. It might be generated as an organic virus in the bodies of others, or it might originate through metabolic tissue-changes in the patient himself, as in the auto-intoxications. The poisonous substance might gain access to the system through the alimentary canal, by the respiratory tracts, or through the cutaneous surface, and it might act directly on the cerebro-spinal centres or the sympathetic nervous system, or through pathological changes which it produced in the blood or the internal organs. The speaker said that the more common means of entrance of the poison were in adulterated food, impure water-supply, and the numberless exposures to noxious agents through special occupations. It was of interest to note that the action of these agents was often most persistent and continuous long after the exposure, and that the variation in effects of the same agent in different individuals was very great. This individual idiosyncrasy was well illustrated in the instance of alcohol, which by some was borne in enormous quantities, while in others the smallest amount would derange mental action. The speaker touched upon gout and lithæmia and their relation to psychic disturbances, and then referred to the auto-intoxicants, the ptomaines or leucomaines, which might cause mental disorders. A number of writers believed that autogenous poisons entered the circulation and acted directly on the central nervous centres with sufficient toxic force to produce mental disorders. He hoped that the day was not far distant when these poisonous alkaloids would be isolated and studied as to their physiological effects, and as to their antidotes, so that at the same time that mental derangement from a special toxic agent was diagnosed, the antidotal remedy for the disease might be suggested.

Dr. Tomlinson wanted to call attention to the fact that a toxic influence could not produce insanity of itself, but if produced, there must have been a pre-existing instability of the nervous organization. The instability might be hereditary or acquired. He looked upon insanity resulting from the misuse of narcotics and alcohol, as a manifestation of defective nervous organization, exaggerated by the toxic influence these substances had upon the organism.

The Sensory and Sensory-motor Disturbances Associated with Insanity.—Dr. H. A. Tomlinson read a paper on this subject. To study understandingly the nature of sensory and motor disturbance in insanity, it was necessary to erect a pathological framework, into which the various manifestations could be fitted more or less accurately; and as the absence of definite lesions in most cases left us no tangible pathological entity upon which to base our deductions, it became necessary to formulate an hypothesis, to explain the functional disturbances which originated and accompanied the perverted and excessive sensory and motor activity in these cases. This apparent absence of definite anatomical change, the speaker believed to be inherent in the conditions which gave rise to insanity, in the fact that the majority of cases of insanity, though furnishing widely different clinical pictures during the earlier manifestations of disease, existed as terminal dementia for a sufficient length of time before death to obscure any definite pre-existing lesion.

For convenience of study, the sensory and motor disturbances associated with insanity might be arranged as follows: Sensory disturbance of general sensation, including anæsthesia, analgesia, paræsthesia, and disturbed muscular sense; disturbances of special senses, including auditory, visual, olfactory, gustatory, and tactual hallucination; illusions, manifested by associated perversions, and lastly visceral hallucination; motor disturbance; tremor, local or general, automatic associated movements, paresis and paralysis, involving special muscular groups or general muscular function, vaso motor disturbance, spasm, and convulsion. Analysis of these different forms of disturbed functional activity seemed to lead inevitably to the conclusion that, even in their most complex manifestations, they were simply the outcome of increased or decreased irritability in the functional nerve-cell. The complexity depended upon the number of functional groups associated. As a summary of the arguments based on his hypothesis, the author thought that the following deductions were logical and warranted: The application of the theory of evolution to the study of the development of the nervous system and of the normal manifestation of its activities, furnished the best and most satisfactory basis for the study of the hereditary and acquired imperfections in its structure. In conclusion, he ventured the opinion that it was in the direction in which the theory of evolution led that we must look for future progress in the study of insanity and its associated disturbances, especially when its prevention and cure were the objects sought, and we must look to biology and physiology, rather than to pathology, for our guide in these studies.

Phthisis in Its Relation to Insanity.—Dr. Thomas J. Mays, of Philadelphia, read a paper with this title. Not only was phthisis more common among the insane than it was among the general population, but facts showed that this disease had a predilection for certain forms of insanity. Thus it was more likely to occur in the depressed than in the exalted types of insanity. Clouston says that this is especially true of melancholia when combined with the monomania of suspicion, and that sooner or later nearly all these cases die of pulmonary phthisis. The speaker's own observation led him to believe that general paralysis, or paretic dementia, was not infrequently associated with phthisis. The most superficial examination of mortality-statistics made it clear that the human constitution was more vulnerable to phthisis at certain periods of life than others, although it was true that those who inherit the disease died three years earlier than those who acquired it. Although asthma was a well recognized disease, its life history had not been investigated with the thoroughness that its importance demanded. The speaker thought that the facts tended to demonstrate that asthma was closely associated with consumption on the one hand, and on the other, that asthma was closely related to insanity. Notwithstanding the great advance in the modern study of the neuroses, the pathologic relationship between the lungs and their nerve supply had been practically ignored. The lungs were innervated by the largest and most important nerve in the body; yet, strange to say, nearly all of the diseases incidental to these organs were at present attributed to the influence of irritants and excitants introduced from without, and the possibility that the fault might reside in this nerve did not even receive serious consideration. The foregoing facts, the speaker thought, established the truth of the proposition that the link that bound pulmonary phthisis to insanity and to other neuroses was a disease of the vagi.

A Case of Akinesia Algera.—Dr. J. J. Putnam, of Boston, described the patients suffering with this condition as experiencing severe pain during or after use of the muscles. They were all neurasthenic. He had a case many years ago for which he had always desired to find some category, and to report when he found such category. He had supposed the symptoms were an exaggeration of those common to nervous patients. The patient referred to was, when seen by the speaker, a middle-aged man, and his trouble had existed since childhood, gradually increasing in severity. He had belonged to a family of nervous invalids. The symptom to which the speaker wished to call attention was excessive pain immediately following the use of the muscles. The man could not walk one-third of a mile without pain coming on upon cessation of exertion. This result was invariable. The pain was situated mainly in the legs, but if the arms were used he would suffer pain in them. There was no sign of any

atrophic changes, the man was well formed, had a delicate skin, and there was no other symptom present. The pain was diffused throughout the muscles of the thigh and below the knee. There was no tenderness.

Cephalic Tetanus.—Dr. J. J. Putnam also described a condition under this name which he says was rarely observed in this country. The patient, after having five teeth filled, had been seized with stiffness of one side of the face and neck. This was followed by spasms so severe that the teeth were ground together. The temperature was 101° F. After some six or eight weeks the symptoms had passed away, but as they abated the opposite side had become involved, but in a less degree. A surgeon who had seen the case thought it was not tetanus, but there was really no reason why the parasite might not have been introduced during the filling of the teeth.

Correspondence.

TO REPRESS EXPECTORATION IN PUBLIC PLACES.

To the Editor of the Medical Record.

Sir: The *Annals of Hygiene* for July gives an extract from the Medical Record, in which Dr. T. M. Prudden is quoted as speaking of the filth and contagion resulting from the American habit of expectoration, and which asks, "Shall we not have a society for the prevention of expectoration?" I should like Dr. Prudden, and the readers of the Medical Record generally, to know that the Women's Health Protective Association, of Allegheny County, has been fighting the spitting nuisance by organized effort for more than a year. By ceaseless importunity, we have induced the managers of the different street-car companies to post placards prohibiting spitting in all their cars, and a noticeable improvement in the condition of these vehicles has already been effected. The Pittsburg, Cincinnati & St. Louis Railroad, and the Allegheny Valley Railroad have placed similar notices in all their local stations, urging men not to spit upon the floor, and we hope that the other railways will in time follow their example. A notice especially prepared for us by the State Board of Health, calling attention to the diseases that are propagated through expectoration, has been neatly printed, and will be posted this fall in every public school-room in Pittsburg, and through the co-operation of the Superintendent of Public Schools the teachers will be instructed to give weekly talks to their scholars with this notice as a text. Forty thousand children will thus be taught not to spit in public.

We hope to get this notice posted also in theatres and other public places.

Our society was formed to agitate the subjects of street cleaning and garbage removal; but we found we could not ignore so conspicuous a violation of hygiene as the filthy and—in Pittsburg—universal habit of public expectoration.

We hope for the continued aid of the Medical Record on this subject. Articles like Dr. Prudden's are also a vigorous assistance to our cause.

Very respectfully,

Mrs. John M. Oakley, *Secretary*.

45 Sixth Street, Pittsburg, Pa.

Medical Journalism in Chili.—The *Revista Medica de Chile* has again begun to appear after a period of suspended animation which lasted for a year. The editor explains his "prolonged silence" by stating that "the persecutions carried on by the Dictatorship against the men of liberty also involved medical practitioners. . . . The shrieks of outraged liberty drowned the sweet voice of science." Several of the collaborators in the *Revista* were sent to prison or had to seek safety in flight, while others took an active part in the fighting, and in the clash of arms not only laws but medical reviews are silent.

New Instruments.

A RETRACTOR FOR AMPUTATIONS.

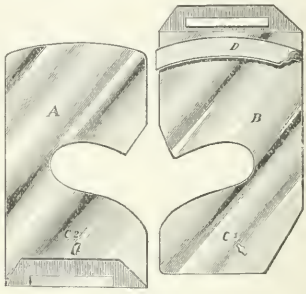
By E. J. Meyer, M.D.,

Buffalo, N. Y.,

Late House Surgeon Buffalo General Hospital.

The accompanying illustration represents a new instrument devised by me for the purpose of retracting the soft tissues previous to dividing the bone in amputations. It is intended to take the place of the various cloth retractors, which are, at their best, very unsatisfactory.

The instrument consists of two separate plates, A and B, united by means of a French lock, bearing curved slot C^1 and C^2, which, by bringing the plates nearer together, can be made to fit any sized bone at will, the instrument when united being made firm by one plate overlapping and fitting into the semicircular groove D.



The advantages of this instrument are as follows: 1. It is comparatively inexpensive. 2. It is readily rendered aseptic, because of its plain construction. 3. It affords a firm support for the bone while manipulating the saw. 4. It completely retracts the tissues, thus allowing a high division of the bone if desired, furnishing a protection of the tissues from bone-dust, and absolutely preventing any tissue laceration.

The retractor has been made for me by Stoddart Brothers, Buffalo, N. Y.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 23, 1892.

	Cases.	Deaths.
Typhus fever	3	0
Typhoid fever	28	14
Scarlet fever	55	7
Cerebro-spinal meningitis	2	1
Measles	219	21
Diphtheria	81	30
Small-pox	4	4
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Death from a Trivial Accident.—The Hon. John Robson, Premier of British Columbia, died recently in London from pyæmia. While driving in a hansom cab, about ten days before, he had accidentally jammed his finger in the door and bruised it severely. A physician examined it but did not consider the accident a serious one. The finger did not heal well, however, and when medical advice was sought again the patient was found to be suffering from pyæmia, and died in spite of amputation of the finger.

DIPHTHERIA AND ALLIED PSEUDO-MEMBRANOUS INFLAMMATIONS—A CLINICAL AND BACTERIOLOGICAL STUDY.[1]

BY WILLIAM HALLOCK PARK, M.D.,

NEW YORK.

(Continued from page 122.)

Pseudo-membranous Inflammations in which the Klebs-Loeffler Bacilli are Never Present.—These will be considered in the following clinical divisions: 1. Extensive pseudo-membranes, mostly confined to tonsils, soft palate, and pharynx: *a*, Uncomplicated; *b*, complicating infectious diseases. 2. Pseudo-membranes involving larynx (as only two of these were complicated by infectious diseases they will be considered with the uncomplicated cases). 3. Pseudo-membranes confined to the tonsils.

Extensive Pseudo membranes, Confinea Chiefly to the Tonsils, Soft Palate, and Pharynx.—CASE I. February 5, 1892.—Polly D——, aged eight. Clinical history: Tonsils covered by large, irregular, adherent, whitish patches. Fauces and tonsils swollen, and livid in color. Temperature, 104° F.; pulse, 40; respiration, 20.

February 6th.—Tonsils, sides and tip of uvula, and faucial pillars covered by a thin, friable, grayish pseudo-membrane, which leaves a bleeding surface on removal. The appearance is as if on a mucous membrane denuded of its superficial epithelium a thick paint had been applied.

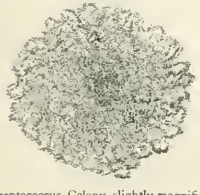
February 7th.—Tonsils and faucial pillars clear of membrane; superficial ulceration on pillars, and adherent membrane to uvula. Temperature remains between 102 and 104° F.; pulse, 118 to 130; respiration, 24 to 30.

February 16th.—Ulceration on uvula nearly healed. Temperature normal. No albumin in urine at any time. No great prostration.

[1] Through an error in last week's issue the descriptions under the sketches of colonies and bacteria were misplaced. They are given correctly below:

Surface Colony of Klebs-Loeffler Bacilli, on Agar Plate, slightly magnified; twenty hours' growth.

Klebs-Loeffler Bacilli, highly magnified.



Streptococcus Colony, slightly magnified; twenty hours' growth.

Streptococci, highly magnified.

Bacterial examination: Cultures were made daily from bits of membrane or swab, but never revealed any Loeffler bacilli. A quick-growing streptococcus which often appeared as a diplococcus was always the most frequent organism present.

CASE II. February 27th.—Charlotte V——, aged nineteen. Clinical history: Both tonsils, and adjacent surfaces of uvula covered by a thin gray membrane. Tonsils much swollen and painful. Great hyperæmia of pharynx. Temperature, 99.6° F.; pulse, 100. No albumin in urine.

February 29th.—All symptoms abated. Membrane disappeared. No swelling of glands.

Bacterial examination: Almost pure culture of streptococci growing in long twisted chains.

CASE III. February 3d.—Rose L——, aged sixteen months. Clinical history: Thin, adherent, semi-translucent membrane on tonsils and adjacent surfaces of uvula. Nostrils occluded, but no membrane visible. Croupy voice and breathing. Slight swelling of glands of neck. Temperature, 100.2° F.; pulse, 136; respiration, 34.

February 4th.—Membrane nearly disappeared. Child nearly well.

February 6th.—Throat perfectly clean. Child is well. Evening temperature, 100° F.; pulse, 118; respiration, 28.

Bacterial examination: Almost pure culture of a streptococcus growing in long chains. A few colonies of a short-chain bacillus.

CASE IV. March 14th.—George M——, aged four years. Clinical history: Five days ago both tonsils removed. Now, on depressed stumps of tonsils, on anterior pillars, and on adjacent surfaces of the uvula is a very thin grayish membrane. Complains of sore throat and not feeling well.

March 8th.—Membrane has disappeared.

Bacterial examination: Plates and tubes gave a pure culture of a rapid-growing streptococcus, often appearing as a diplococcus.

CASE V. March 25th.—Woman, aged twenty-four. Case from Presbyterian Hospital. History of sore throat and pseudo-membrane for a week. Clinical history: Pharynx and tonsils swollen and livid red in color. Considerable pain on swallowing. Thin, flaky, whitish pseudo-membrane on the sides of the uvula, extending up a short distance on the soft palate, where the swelling has caused creases of the tissues, also similar-looking patches on the tonsils and pharynx. Temperature range, 100 to 101.5° F.

Bacterial examination: Many colonies of the long-chained streptococcus.

CASE VI. February 6th.—Margaret M——, aged twenty months. Clinical history: Uvula and lateral walls of pharynx covered by thin, adherent patches.

February 8th.—Still remain on uvula. Temperature varies between 99 and 101° F.

February 11th.—Throat clean.

Bacterial examination: Cultures reveal many colonies of the long chained streptococcus.

This case has an extremely interesting history. The child was exposed to scarlet fever for three hours just before its admission to the diphtheria wards of the hospital. On the eighth day the child developed scarlet fever. In two other cases, with similar throats, the children showed slight desquamation and are therefore con-

sidered as complicating scarlet fever. In this case the history excludes such a supposition.

Case VII. February 3, 1892.—Gussie G——, aged nineteen. Clinical history: Hyperæmia of whole pharynx and tongue. Adherent thin grayish-white membrane on sides and tip of uvula. A few small grayish deposits on left tonsil. Temperature, 101° F.; pulse, 98. On fifth day, no membrane; feels well; sixth day, discharged. Temperature, only on two days above 100° F. On the fourth day, trace of albumin in urine.

Bacterial examination: Cultures contained no colonies of the Loeffler bacilli, but many colonies of the long-chained streptococcus.

Case VIII. February 3d.—Jennie K——, aged eighteen. Clinical history: Thin adherent pseudo-membrane on sides and tip of uvula. Some hyperæmia of pharynx. Temperature, 101.4° F.; pulse, 100. Membrane remained four days. After the first day, temperature and pulse sank to the normal, and patient did not appear sick. No albumin in urine. Discharged on the sixth day.

Bacterial examination: Cultures revealed many colonies of the long-chained streptococcus and numerous others of various forms.

Case IX. February 2, 1892.—Mary D——, aged twenty-one. Clinical history: For the past three days, pain on swallowing and on opening mouth. Posterior half of left tonsil, and post pillar, and most of uvula, covered by a thin grayish-white membrane, easily removed, leaving only a few bleeding points. No appreciable ulceration. Temperature, 102° F.; pulse, 108; respiration, 26. Glands of neck on left side swollen.

February 25th.—Still thin white membrane on both tonsils and adjacent surfaces of uvula.

Bacterial examination: Plates and tubes gave a pure culture of the streptococcus.

Five other cases gave histories and lesions so similar to the above that it seems needless to give them in full.

Summary.—These fourteen cases present such uniform clinical appearances and histories that they deserve to be considered by themselves. The ages ranged from twenty months to twenty-one years. In no case was any clear history of infection obtained, or of exposure to scarlet fever or measles. The considerable duration, three to eleven days, averaging five days, is important.

In these cases there is first a redness and swelling of the mucous membrane of the pharynx, tonsils, and fauces, with later a thin purulent discharge. Cultures at this time reveal very abundant colonies of streptococci. The epithelium of the inflamed mucous membrane, where the irritation is intensified by the contact and friction of adjacent surfaces, becomes necrotic, and the denuded surface becomes covered by a thin pseudo-membrane, composed mostly of streptococci held together by a small amount of fibrin. The streptococci may also penetrate into the denuded mucous membrane.

If one looks at a well-marked case, having the patient open the mouth slightly, and depresses the tongue just a little, one will notice the inflamed uvula lying between and against the swollen tonsils. On the portions of the uvula thus irritated by contact, on the faucial pillars lying against the tonsils, and, in extreme cases, on the lateral walls of the pharynx and on the soft palate spreading up from the sides of the uvula, one finds this pseudo membrane which is always light grayish in color, thin, and friable. On removal, a bleeding surface is disclosed. When astringent applications are not used, the membrane usually disappears gradually, and does not scale off in firm pieces of considerable size, as in many cases of true diphtheria.

In none of these cases was there a fatal result; neither great prostration, after-emaciation, nor paralysis. Except that these cases were never complicated by suppuration of the cervical glands and diffuse cellulitis, they otherwise appear to be the same as the pseudo-membranous inflammations complicating scarlet fever, the greater severity in the latter being probably due to the influence of the scarlet fever. The temperature curve varied greatly in the different cases. In these fourteen cases the bacteriological diagnosis was of great value in prognosis, for pseudo-membranes, so extensive in true diphtheria, would have made it grave.

Pseudo-Membranous Inflammations Complicating Scarlatina.—Confined chiefly to tonsils, soft palate, and pharynx. Seventeen of these cases were repeatedly examined. Except for complications, these gave exactly the same clinical appearances as those not complicating infectious diseases. Only six illustrative cases will be given.

Case I. February 29th.—James F——, aged two and one-half. History of scarlatinal rash. Died. Clinical history: Slight desquamation on hands. There is a thin, gray, adherent membrane on tonsils. Temperature, 100° F.

March 3d.—Thin, clean, grayish membrane on sides and tip of uvula.

March 7th.—Throat clean.

March 15th.—This child, with two others in the ward, to-day showed a re-formation of the membrane on tonsils and uvula.

March 16th.—Considerable laryngeal dyspnœa. Membrane persists.

March 18th.—Intubated. Bronchial râles over chest. Temperature, 101 to 103° F.; pulse, 130 to 150; respiration, 35 to 60. Broncho pneumonia.

March 21st.—Left cheek and lip swollen and œdematous.

March 23d.—Extensive ulceration of mucous membrane of left cheek. Child very weak. Temperature and pulse remain high.

March 25th.—Tube removed. Membrane disappearing. Less swelling in face. Seems somewhat better.

March 31st.—Gradually grew weaker, with continued high temperature, until death.

Case II. February 9th.—Frank McM——, aged two. Membranous rhinitis with pharyngitis. Death. Clinical history: Slight membrane on lateral walls of pharynx. Thick, whitish, succulent membrane blocking up both nostrils. Glands of neck swollen.

February 12th.—Marked increase in inflammation of glands and periglandular tissues. Pharynx clean. Disintegrating membrane in nose.

February 20th.—Glands suppurated. Had irregular high temperature, 102 to 105° F. Pulse above 150. Died in septic condition.

Bacterial examination: Markedly twisted streptococcus, almost in pure cultures. No Loeffler bacilli ever present. Bouillon clear, with flocculent sediment.

Case III. February 9th.—Edna K——, aged two and one-half. Death. Clinical history: Tonsils, adjacent edges of faucial pillars, and borders of uvula, covered by a thin, pearl-colored pseudo-membrane, which, when removed, reveals ulcerations. Rash. Temperature, 103° F.; pulse, 156; respiration, 34. Patient died on the 18th with high temperature, pulse, and respiration.

Bacterial examination: Very numerous colonies of the long-chained streptococci and nearly as many of the staphylococcus pyogenes aureus.

Case IV. February 7th.—William W——, aged seven. Had had scarlet rash and high temperature. Recovered. Clinical history: On 18th, thin, whitish membrane adherent to tonsils. Glands of neck swollen.

February 27th.—Incision of suppurating glands. Tonsils clean.

February 29th.—Better in every way. Temperature remained between 99 to 101° F.

Bacterial examination: From throat and from glands a streptococcus, in long twisted chains, was obtained. From the thin purulent serum from the glands a pure culture was secured.

Case V. February 23d.—Annie O'H——. Recovered. Clinical history: Scarlet rash; no fever; slight hyperæmia of throat.

March 17th.—When apparently well, developed a thin, dirty-white membrane on tonsils, which left a raw surface on removal.

March 19th.—Considerable ulceration of tonsils, and marked induration of glands of neck, with tenderness.

March 25th.—Membrane disappearing.

From swab of throat on February 23d nearly pure culture of the streptococcus longus. From bit of membrane, March 19th, almost pure culture of colonies of a streptococcus, appearing as a diplococcus and in short rows under the microscope.

Case VI. February 18, 1892.—Rose C——, aged three and a half. Died. Clinical history: Child looks very ill. Thin, soft membrane on sides of uvula, anterior pillars, and lateral walls of pharynx. When removed, leaves bleeding, ulcerated surface. Glands of neck swollen.

February 21st.—Membrane nearly gone, superficial ulceration on sides of uvula. Glands hard, indurated, and much swollen. Died on 22d. Temperature varied between 103 and 105° F.; pulse, 160 to 170; respiration, 44 to 58.

Bacterial examination: Almost pure culture of the streptococcus.

Summary and Remarks.—In 11 other cases of similar soft membrane on faucial pillars, edges of uvula, and tonsils, by far the most numerous colonies were those of the long chained streptococci. In one case a streptococcus, similar to that occurring in the late membrane in Case V., was present. From 2 cases of follicular tonsillitis, and from 8 cases, without exudation, in which hyperæmia of pharynx and scarlet rash were present, abundant streptococci were invariably found. In none of the cases were the Loeffler bacilli found. Of the 10 cases of scarlet fever, in which the complicating croupous inflammation appeared early, 6 died. In the 7 in which it appeared late, all recovered. In the 6 fatal cases, 2 had extensive gangrenous cellulitis, beginning in the neck, spreading over the chest, and causing the sloughing of an extensive portion of skin. A third had diffuse suppuration in and about the cervical glands.

The presence of streptococci growing in long twisted chains in the throats of all the cases examined during the period of the eruption is very noteworthy, and strongly indicates the necessity of carefully looking after the cleansing of the throats, whether any visible membrane is present, or not. The fatal result in some seemed to be due more to the complicating cellulitis and abscesses than to the scarlatina. The possibility, suggested by some observers, that the streptococci may be the cause of scarlet fever, is worthy of investigation. It would take very strong evidence, and necessitate finding some constant differences between the streptococci occurring in scarlet fever and those appearing so frequently in other conditions, or the proof that they can at one time cause scarlet fever and at another a local lesion in the throat. It would seem more probable that the infectious diseases, especially scarlet fever and measles, favor the development and growth of the streptococci, known to be so frequently present in both the healthy and inflamed throat.

In three of the children who were entirely convalescent the pseudo-membranous inflammation seemed to be the result of an infection from others in the ward. The pseudo-membrane lining the nasal cavities in Case II. is interesting, indicating that some cases of membranous rhinitis are due to streptococci.

Pseudo membranes Involving Larynx caused by Streptococci.—Case I. February 13th.—Hattie S——, aged five. Recovered. Clinical history: On admission, cyanotic from laryngeal obstruction; intubated, relieved; very slight, adherent, thin, pearl-gray patches on uvula. Temperature, 100° F.; pulse, 102; respiration, 22.

February 17th.—Patient never seemed sick; exudation on uvula disappeared; no albumin in urine; tube remained in five days.

Bacterial examination: Plates and tubes, made on two days, showed no Loeffler bacilli, but many colonies of a long chained streptococcus and scattering forms.

Case II. February 14th.—Nochem E——, aged six. Recovered. Clinical history: Admitted with marked laryngeal stenosis; intubation gave perfect relief; no membrane visible. Temperature, 101° F.; pulse, 132; respiration, 34. From time to time some difficulty in breathing, which was relieved by calomel fumigation. For one week temperature varied between 99 and 101° F.; pulse, 100 to 126. Never any visible membrane. No albumin. Tube removed on the fifth day.

Bacterial examination: No Loeffler colonies found on plates or tubes made from swabs of pharynx and tonsils taken on the first three days; numerous streptococci.

Case III. March 16th.—Osthof ——, aged three and one half. Recovered. Clinical history: Admitted with marked laryngeal dyspnœa; vomited, was fumigated, but without relief; intubated; both tonsils covered by a nearly white, thin, adherent membrane. Temperature, 101° F.; pulse, 128; respiration, 30.

March 19th.—Still extensive patches of same membrane on tonsils; breathes fairly well; no prostration. On second day temperature reached 103° F. Now 99° F.

Bacterial examination: Numerous colonies of streptococci; none of Loeffler bacilli.

Case IV. March 18th.—Esther F——, aged one. Recovered. Clinical history: Very small white patch, slightly adherent to right tonsil; laryngeal dyspnœa; made to vomit, and fumigated with calomel, but without relief; intubated five hours after arrival. Temperature, 99.6° F.; pulse, 120; respiration, 30.

March 20th.—Seems about well; tube still retained; some albumin in urine.

March 26th.—Tube removed; temperature never above 100° F.

Bacterial examination: Cultures gave abundant colonies of the long-chained streptococcus.

Case V. March 19th.—Morris G——, aged four. Died. Clinical history: Intubated before admission. Temperature, 100° F.; pulse, 130; respiration, 32. No membrane visible in throat; some white, flaky membrane coughed up; large amount of albumin in the urine.

March 22.—Chest full of râles; child drowsy and cyanotic, although there is no laryngeal obstruction. Temperature, 102° F.; pulse, 150; respiration, 42. Swallows with difficulty. Died on 23d.

Bacterial examination: Abundant colonies of long-chained streptococcus and many of micrococci and other scattering forms.

Case VI. March 21st.—Margaret F----, aged four. Clinical history: Marked laryngeal dyspnœa on arrival, intubated one-half hour later; large piece of thin, crumbling membrane coughed up through tube; swollen tonsils, with small whitish patches. Temperature, 99.4° F.; pulse, 104; respiration, 26.

March 24th.—Tube removed; seems well; highest temperature, 101° F. No albumin in urine.

Bacterial examination: Cultures from swabs and from membrane coughed up had many colonies of long-chained streptococci and some of streptococci appearing in short rows and as diplococci.

Case VII. March 30th.—Katie F——, fifteen months, sister of last. Clinical history: Five days before admission slight cough, next night awoke suddenly with croupy cough. The laryngeal symptoms increased from night to night. Intubated shortly after admission. Temperature, 100.2° F.; pulse, 112; respiration, 28. Thin whitish deposits on tonsils.

April 1st.—Had an attack of marked laryngeal dyspnœa, requiring the removal of the tube. Attached to it was a long piece of membrane. Temperature, 103° F.; pulse, 144; respiration, 30. Restless.

Patient developed broncho-pneumonia. Temperature remained high. Tube was removed on the eighth day. Died on April 10th.

Bacterial examination same as in last.

These two cases occurring in the same family, one eight days after the other, point to the possibility at least of a direct transmission of the contagion.

CASE VIII. March 3d.—Jennie P——, aged eleven months. Intubation. Death. Clinical history: Slight patches on tonsils, laryngeal dyspnœa. Whole lower face badly burned, through attempt of mother to give it steam inhalations. Child looks badly. Moist râles over whole chest. Glands of neck slightly swollen.

March 4th.—Intubated. The tube keeps clogging with thick purulent fluid. Dyspnœa increased, and child died at midnight.

Bacterial examination: From first day many streptococci, and many colonies of a quick-growing micrococcus, which liquefied gelatine and coagulated milk. The growth on the media was entirely different from the staphylococci. From trachea, after death, an almost pure culture of the micrococci was obtained.

CASE IX. March 17th.—James F——, aged two and one-half. Intubation. Death. Clinical history: On account of a previous history of scarlet fever, this case has been described under the scarlatinal class.

CASE X. March 19th.—William M——, aged thirty. From Presbyterian Hospital. Clinical history: No specific, alcoholic, or nephritic history. Symptoms began on the morning of the day admitted. When admitted, patient was suffering from laryngeal dyspnœa. Examination revealed much swelling and redness of whole larynx, also a small patch of moist membrane on arytenoids.

March 21st.—Dyspnœa was so bad on the 20th as to nearly call for tracheotomy. To-day breathing easier. Soft, dirty-gray membrane persists on swollen arytenoids. Small patches, also, on the false cords and epiglottis. Membrane disappeared after two days, and patient recovered. The orderly who attended the patient developed a marked follicular tonsillitis. In both these cases the most numerous colonies were those of the streptococcus growing in long twisted chains.

CASE XI. April 27th.—Andrew I——, aged forty-three. Death. On admission the history is obtained from friends that he has been three days sick. He is weak, slightly delirious, and appears as if suffering from some severe infectious disease. The whole uvula and the portions of soft palate adjacent to it are covered by a very thin, dirty covering which can hardly be called a pseudo-membrane. The whole pharynx and palate are extremely hyperæmic. Patient is hoarse, and has some laryngeal dyspnœa. Temperature, 103° F.; pulse, 128; respiration, 26. Patient became violently delirious, and died the next day. No autopsy.

This case is interesting as it is the only fatal one in adults. It is probable that the croupous inflammation was only a complication of some one of the infectious diseases.

Pseudo membranous Laryngitis, not True Diphtheria.—Table of Cases.

Number.	Name.	Age.	Disease and complications.	Temperature, pulse, and respiration on arrival.	Length of time intubated.	Result.
1	Hattie S.	5 years.	Croupous laryngitis; croupous patch on uvula.	Temp., 100; pulse, 102; resp., 22.	Membrane remained 4 days; intubated for 5 days.	Recovered.
2	Nochem E.	6 years.	Croupous laryngitis.	Temp., 101; pulse, 132; resp., 34.	Tube removed 5th day.	Recovered.
3	Harry O.	3½ years.	Croupous laryngitis; croupous tonsillitis.	Temp., 101; pulse, 128; resp., 30.	Tube removed 5th day.	Recovered.
4	Esther F.	1 year.	Croupous laryngitis; croupous tonsillitis.	Temp., 99; pulse, 120; resp., 30.	Tube removed 8th day.	Recovered.
5	Rosie B.	3½ years.	Croupous laryngitis.	Temp., 99; pulse, 116; resp., 24.	Tube removed 3d day.	Recovered.

Pseudo-membranous Laryngitis, not True Diphtheria — Table of Cases.—Continued.

Number.	Name.	Age.	Disease and complications.	Temperature, pulse, and respiration on arrival.	Length of time intubated.	Result.
6	Morris G.	4 years.	Croupous laryngitis; bronchopneumonia.	Temp., 102; pulse, 150; resp., 42.	Intubated before admission; lived 4 days.	Died.
7	Jennie P.	11 mos.	Croupous laryngitis; croupous tonsillitis; scald of face; bronchitis.	Temp., 103; pulse, 150; resp., 40.	Intubated with but slight relief; lived 1 day.	Died.
8	James F.	2½ years.	Extensive pseudo-membrane in throat; cellulitis; croupous laryngitis; broncho-pneumonia.	Temp., 100.	19 days after admission intubated; removed after 7 days.	Died.
9	Barney S.	2¾ years.	Croupous laryngitis; developed measles 8th day.	Temperature, 101.4; pulse, 106; resp., 38.	Intubated; removed 8th day.	Recovered.
10	Wm. C...	2 years.	Croupous laryngitis; croupous rhinitis.	Temperature, 101.4; pulse, 128; resp., 38.	Intubated; removed 8th day.	Recovered.
11	Bert. P..	4 years.	Croupous laryngitis.	Temp., 104; pulse, 144; resp., 48.	Intubated.	Recovered.
12	Kate F...	15 mos.	Croupous laryngitis; croupous tonsillitis; broncho pneumonia.	Temperature, 100.2; pulse, 112; resp., 28.	Intubated; lived 11 days.	Died.
13	Margt. F.	4 years.	Croupous laryngitis; croupous tonsillitis.	Temp. 99.4; pulse, 104; resp., 26.	Intubated half an hour after admission; removed after 3 days.	Recovered.
14	Harris A.	3 years.	Croupous laryngitis.	Temp. 101; pulse, 144; resp., 40.	Intubated on admission; removed 6th day.	Transferred for measles 9th day.
15	Wm. F..	30 years.	Croupous laryngitis.	Moderately high temperature.	Marked dyspnœa.	Recovered.
16	Andrew J.	43 years.	Croupous laryngitis; pharyngitis, etc.	Temp., 103; pulse, 128; resp., 26.	Patient died in 24 hours; apparently had some infectious disease besides croupous inflammation.	Died.

Fourteen of these 16 were in young children. In 5 of the 16 no deposit or membrane was visible above the larynx. Four of the 5 deaths were due to lung complications.

Summary.—These sixteen cases, occurring in four months, prove that membranous croup is frequently an independent disease, having no connection with true diphtheria. In only two was any connection with scarlet fever or measles discovered. On admission, a diagnosis from clinical history and appearance was impossible.

In the majority of the nine cases that recovered, the course of the disease was mild After intubation had relieved the dyspnœa, the patients never appeared dangerously ill. By the third day they were sitting up in their beds and playing with their toys. The temperature averaged somewhat higher during the first days than in the cases of laryngeal diphtheria, and rose to 103 and 104° F. when the lungs became involved.

In two of the children a pretty clear history of direct infection from other cases was obtained. In croup, the magical effect of intubation is seen, for without tracheotomy or intubation the majority would certainly have died. The good percentage of recovery, 66⅔ per cent., in these cases, as contrasted with intubation in diphtheritic laryngitis, thirty per cent., throws much light on the problem why at certain times and in certain countries the percentage of recoveries is so much greater than in others. It also forces the query whether, in the future, all cases should not be examined bacteriologically, if the statistics are to be valuable. Broncho pneumonia seems to be the most frequent cause of death.

Pseudo-membranes Confined to the Tonsils Caused by Streptococci.—CASE I. March 3, 1892.—Genet M——, aged six. Clinical history: From an asylum with three other cases. Right tonsil is swollen and covered by a

thick, adherent, gray-colored, fibrinous pseudo-membrane. Cervical glands considerably swollen on right side. Slight pain and tenderness. Temperature, 101° F.

March 5th.—Still thick membrane on tonsil. Nowhere else. Feels well.

March 7th.—Tonsil clean. Is slightly croupy.

March 9th.—Perfectly well.

Bacterial examination: Cover-glass made from smear of membrane showed very numerous cocci in pairs, singly, and in chains. Also a few bacilli. Plates gave an almost pure culture of the long-chained streptococcus. Nothing found in anyway similar to the Klebs-Loeffler bacillus.

CASE II.—Mark C——, aged four. From same asylum. Clinical history: Pseudo-membrane on upper portion of left tonsil and adjacent surface of anterior and posterior pillars. Well on third day. No fever.

Bacterial examination: Mostly streptococci.

CASE III. March 5, 1892.—Lottie E——, aged twenty-one. Clinical history: Both tonsils are nearly covered by irregular, semi-adherent pseudo-membranous patches. Considerable swelling and hyperæmia. No swelling of glands. Not much pain; slight constitutional symptoms. Temperature, 101° F.

March 7th.—Tonsils nearly clean. Feels well.

March 8th.—Perfectly well.

Bacterial examination: Many colonies of the long-chained streptococcus and other scattering forms.

CASE IV. March 12th.—Charles F——, aged thirty. Clinical history: Two days ago felt pain and soreness in region of tonsils. Went to Bellevue, and was sent to Charity Hospital. From there taken to the Willard Parker Hospital. Both tonsils covered by a dirty-brownish smear which is readily removed, leaving irregular patches on tonsils. Pharynx covered by thick, purulent discharge. Tonsils and peritonsillar tissues are much swollen, and the whole pharynx and fauces hyperæmic. Considerable swelling of glands of neck. Temperature, 102° F. Great pain on swallowing and on opening mouth.

March 14th.—Still considerable swelling and hyperæmia, but membranous deposits have nearly disappeared. Feels much better.

Bacterial examination: Reveals mostly colonies of the long-chained streptococcus.

CASE V. March 13th.—Mary C——, aged four. Clinical history: This child is from the same asylum in which four cases occurred ten days before. Both tonsils are swollen, and covered by thick masses of exudate. Temperature, 101.4° F.

March 16th.—Tonsils are clean. Patient feels well.

Bacterial examination: Plates give nearly pure cultures of the long-chained streptococcus.

CASE VI. March 14th.—Annie E——, aged six. Clinical history: Both tonsils covered by irregular patches of pseudo-membrane, with intervening portions smeared with purulent discharge. Considerable swelling of tonsils. Almost no constitutional disturbance.

March 16th.—Tonsils almost clean.

Bacterial examination: The great majority of the colonies are of streptococci.

CASE VII. March 7th.—George M——, aged thirty-one. Clinical history: Felt chilly and depressed two days ago. The next day his physician on examination found the tonsils swollen and covered with a semi-adherent soft deposit. He was referred to the Board of Health. The first examiner thought it a doubtful case, referred it to a second, who pronounced it true diphtheria. On admission, condition the same. Glands of neck somewhat swollen.

March 8th.—Throat is clear, and he feels well.

Bacterial examination: Majority of colonies, streptococci in long twisted chains.

CASE VIII. March 11th.—Land F——, aged twenty-two. Clinical history: History of recurrent attacks of sore throat similar to present one. Swollen, irregularly excavated tonsils, with a few irregular, gray deposits. Pain on swallowing and opening mouth.

March 14th.—Right tonsil nearly covered by dirty adherent pseudo membrane. Left, follicular deposits. Less pain and tenderness.

March 16th.—Still small deposits on tonsils.

March 18th.—Tonsils clean.

Bacterial examination: The most numerous colonies are of a rather quick-growing streptococcus which occurs as a diplococcus and in short chains of diplococci.

Summary.—This disease is so familiar that it is unnecessary to give more illustrative cases. In the 159 here studied 58 are included under this heading. This comparatively large number would seem to indicate that in adults, thick croupous patches, adherent or not adherent, if confined to the tonsils, after twenty-four hours very rarely have anything to do with true diphtheria. The same bacteria (the streptococci) which under certain influences cause an inflamed throat or a follicular tonsillitis, under others seem to produce a croupous tonsillitis. In several cases two members of a family were affected, one with the former, the other with the latter disease. In a few others a very complete history of direct transmission of the contagion was obtained. The croupous deposit, or pseudo-membrane, lasted from two to seven days. All cases recovered without complications.

The intimate connection of some cases of croupous tonsillitis with scarlet fever is brought out in the following examples:

Rose F——, aged twenty-one, was admitted, with marked croupous tonsillitis with constitutional and local symptoms, on May 20th. The three previous days she had taken care of a child sick with scarlet fever, and on the last day also of the mother, who was attacked with croupous tonsillitis. Both she and the mother had come in frequent direct contact with the child.

Two physicians attended a gentleman sick with malignant scarlet fever and croupous tonsillitis. Both were attacked with croupous tonsillitis, and one with scarlet fever also.

The streptococci, found in the pseudo-membranes, presented some striking differences. By far the most frequently present was a streptococcus showing similar morphological and biological traits to the streptococcus pyogenes and erysipelatus. This streptococcus was present in all the scarlatinal cases during the eruption. From the different cases the cultures presented some minor differences in the size of the colonies and the appearance of the flocculi in the broth. The pathogenic qualities varied greatly. Inoculations in rabbits from some produced abscess and necrosis, from others merely slight redness and swelling.

During the last two months, cultures from a number of cases presented a coccus which formed larger colonies than the long-chained streptococcus on the agar plates, producing colonies with nearly even edges, of a coarse, granular, and blotched appearance. Here and there, from their edges short runners sprouted out, and in some cases short twisting loops.

In bouillon, at 37° C., the growth of this streptococcus is vigorous, forming, in twenty-four hours, considerable gray sediment, with cloudy bouillon. Microscopical examination reveals diplococci in pairs and short rows of four to eight. In gelatine tubes the growth does not differ from that of the streptococcus pyogenes except in that it is somewhat more vigorous. The few animal experiments made indicated it to be less pathogenic than the long-chained streptococcus in rabbits. Injected in the ears of rabbits it produced redness and swelling, from the second to the fifth day, with very slight or moderate fever. The rabbits after the fifth day seemed well. Intravenous inoculation was without effect in two cases. A third variety differed only from the first, in that the loops were less twisted. One of these forms, usually the first, was the most abundant micro-organism present in every one of the cases examined, in which the Klebs-

Loeffler bacilli were absent. And in cases of true diphtheria they were usually present in greater or lesser numbers.

The staphylococcus pyogenes aureus was only irregularly present in the cases examined, and only abundant in five. In these, from the blood-serum tubes alone one would have judged that they were the most abundant form of bacteria, but an early inspection of the plates under the microscope revealed the tiny colonies of the streptococci to be present in far the greater number.

In those cases in which suppuration of the cervical glands and extensive cellulitis was present, the long-chained streptococci were always found, except for such complications the special form of streptococci present seemed to exert no influence on the severity or length of the disease.

General Summary.—*Bacteria.*—In 159 cases of pseudo-membranous inflammations there were 54 in which the Klebs-Loeffler or diphtheria bacilli were present, usually as the only or most numerous form of bacteria. With them were often associated streptococci and other micro-organisms. In every one of the remaining, streptococci were the most abundant bacteria, and often the only ones. From various pseudo-membranes the streptococci obtained differed in manner of growth and pathogenic action. The staphylococci were often entirely absent, at other times present in moderate numbers, but never in excess of the streptococci.

Location of Lesion.—In both diphtheria and pseudo-diphtheria the pseudo-membranes occurred on the mucous membrane of the nose, pharynx, larynx, soft palate, and tonsils. In both, the tonsils were the parts most frequently involved. The nasal cavities were more often involved in true diphtheria.

Mortality.—In true diphtheria, 46½ per cent.; in pseudo-diphtheria, 5⅔ per cent.; intubation in diphtheria, 70 per cent.; intubation in pseudo-diphtheria, 28½ per cent.; adults in diphtheria, 36 per cent.; adults in pseudo-diphtheria, 2 per cent.

Contagiousness.—In quite a large proportion of cases evidence was obtained of the direct spreading of diphtheria through contact with infected persons and clothing. In only a few cases of pseudo-diphtheria was equally strong proof obtained. Children sent away from diphtheria for safety, carrying with them their infected clothing, were in a number of cases a source of danger to the families who received them.

Clinical Observations.—It is important at the outset to remember that true diphtheria is frequently associated with pseudo diphtheria, and this mingling of the two adds greatly to the clinical difficulties. Severe uncomplicated pseudo membranous laryngitis may be either true or pseudo diphtheria. The early clinical diagnosis is usually impossible. Low temperature, great prostration, and heart failure point to true diphtheria. A high temperature, lung complications, and no history of infection are in favor of pseudo-diphtheria.

Death occurred usually early, due to heart failure in diphtheria; usually later, due to broncho-pneumonia, in pseudo-diphtheria. In both, early death from suffocation may occur, if intubation or tracheotomy is not performed.

Membranous rhinitis is usually a very mild form of diphtheria having a good prognosis. Membranes complicating scarlet fever are seldom true diphtheria. Pseudo-membranes and thick deposits well developed on, but confined to, the tonsils of adults are nearly always pseudo-diphtheria. Follicular deposits confined to the tonsils in adults are probably always pseudo-diphtheria. Small or large, thick or thin, firmly or slightly adherent patches confined to the tonsils or extending to the larynx in young children may be either true or pseudo-diphtheria, and the clinical diagnosis is often impossible during any time of the disease. Extensive thin, grayish pseudo-membranes, occurring only on those surfaces of the uvula, tonsils, and faucial pillars which lie in contact were always pseudo-diphtheria. The prognosis is good in these cases, except when there are early complications of infectious diseases.

The thick grayish or grayish-yellow pseudo-membranes which cover a large portion of the soft palate and tonsils, often involving naso-pharynx and nostrils, were always the lesion of true diphtheria. These cases were often fatal in both children and adults.

Conclusions.—The results of previous investigations, with the addition of that brought out in these studies, seem to force on us the conclusion that there are two great divisions of pseudo-membranous inflammations, one caused by the Klebs-Loeffler bacilli and the other by some form of streptococci. The few cases in which the pneumococcus of Fraenkel or other cocci seem the cause naturally fall in the second division.

The first is, from beginning to end, a local process, and its lesions are due to the effects of the poison formed by the bacilli in the pseudo-membrane. It is dangerous at all periods of life. The second is also at first a local lesion, but may at any time become a general infection. It is peculiarly liable to cause broncho-pneumonia in children. Both diseases are frequently associated together. Both are directly contagious, though in different degrees.

These two diseases, caused by different bacteria and differing in so many points, should no longer be called by the same name. The name diphtheria will probably be agreed upon by all for those cases in which the Klebs-Loeffler bacilli are present, whether alone or associated with other bacteria.

For the second division some name will have to be agreed upon; whether the streptococcus will be found to be in such a majority the cause that the name streptococcus diphtheria can be applied to it, only further investigation can determine. Perhaps at present the term pseudo-diphtheria will be acceptable.

In all cases where the diagnosis is in doubt, bacteriological examination should be made, because:

1. A correct diagnosis should always be sought for.

2. Without it, all attempts to learn from statistics the worth of special forms of treatment and methods of prevention are well-nigh useless from the frequent incorrectness of the diagnosis. The fact that during four months less than one-third of the cases sent to the diphtheria wards of the hospital had true diphtheria, is sufficient proof of the difficulty of making a clinical diagnosis.

3. It is a great help to prognosis and rational treatment in the more severe cases and enables us to take measures more effectually to prevent the spread of the contagion.

4. It is certain, can frequently be made immediately, and always within twenty hours.

The amount of familiarity with bacteriological work and the appliances necessary, although not very great, are still enough to prevent the great majority of physicians from undertaking it themselves. As the early detection of diphtheria is important for the general health, and as this disease occurs most frequently and is most dangerous among the crowded poor, who are unable to pay for special examination, it would seem peculiarly the business of the Boards of Health to undertake it. In small cities some central places could be selected where the necessary appliances could be kept, in large cities several would be necessary. From these laboratories a properly equipped man could be called to make the cultures and give the bacteriological diagnosis. Children's hospitals and those for infectious diseases should certainly give their pathologist the means to do this.

To insure the safety of those not having diphtheria, these hospitals should have wards separated, where doubtful cases could be kept for twenty-four hours until the diagnosis was made certain by bacteriological examinations. Where this is impossible, experience at the Willard Parker Hospital has shown that general cleanliness and antiseptic irrigation of the nasal and pharyngeal mu-

cous membranes is sufficient in the great majority of cases to prevent the spreading of diphtheria. Care should be taken not to expose small children to pseudo-diphtheria, for it is undoubtedly contagious under favorable conditions and is in them dangerous.

I wish, in closing, to express my gratitude to Professor T. Mitchell Prudden, Director of the Pathological Laboratories of the College of Physicians and Surgeons of Columbia College, New York, for his kindness in making many valuable suggestions and in affording me every needed laboratory facility for these investigations.

I also wish to thank Dr. T. W. Lester, Resident Physician to the Willard Parker Hospital, for his help in the clinical part of these studies, and for the use of the hospital charts.

128 West Eleventh Street, July 1, 1892.

Explanation of Plate.

Figs. 1 and 2 show cultures from same diphtheritic membrane—1, with numerous; 2, with fewer colonies. The more numerous colonies are composed of diphtheria bacilli; the larger whiter ones of non-pathogenic bacilli.

Fig. 3, pure culture of diphtheria bacilli from tissue of inoculated guinea-pig.

Fig. 4, culture obtained by pressing a portion of a soiled sheet, removed from a diphtheria patient, against the media surface. Many varieties of bacteria grew. The smaller colonies are diphtheria bacilli and streptococci.

Fig. 5, a pure culture of streptococci from scarlatinal membrane.

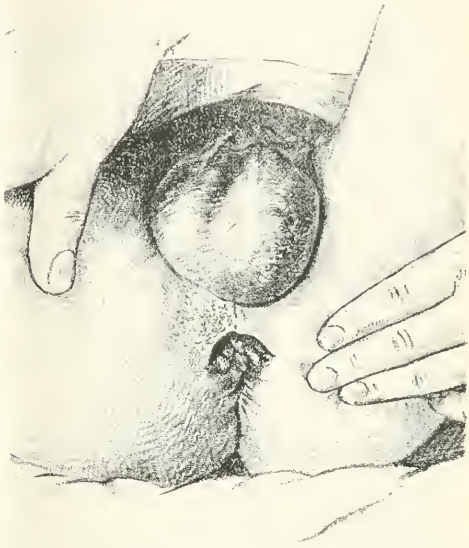
Fig. 6, culture from croupous tonsillitis. The exceedingly small colonies are streptococci. Some of moderate size, staphylococci. No diphtheria. In both 5 and 6 the condensation water has swept the bacteria over the plate surface, making a diffuse growth of colonies.

A NEW METHOD OF REMOVING THE PROSTATE GLAND.

By J. S. PYLE, M.D.,

canton, o.

On April 6th a case of enlarged prostate gland came to my hospital for an operation. The patient was John W——, of Bluffton, Ind., aged seventy years; bodily vigor, fair, but not such as would warrant an operation of great gravity. The walls of the bladder retained their usual contractile power, but the urethral canal was so compressed from the hypertrophied prostate that only the smallest soft-rubber catheter could be inserted to empty the bladder of urine. I planned an operation to suit the physical needs of the patient, feeling assured that the supra-pubic operation of Dr. E. L. Keys, and the lateral incision as in the lithotomy operation described by him and others, were surgical proceedings that my patient could not well endure. An acquaintance with the anatomy of the rectal and perineal spaces soon suggested that a much simpler operation than either of the above was posssible; and forthwith I proceeded to satisfy myself by a process of reason that I was not on the side of fancy, but real possibilities. The space immediately in front of the rectum and behind the bulb of the urethra was chosen as the route through which to reach the base of the bladder and prostate gland. The transverse diameter of the outlet of the pelvis at this point is too short to work in, and consequently it behooved me to increase the operating space without doing injury to important structures. I accomplished this by making a semicircular incision, as is shown in the cut, from a point midway between the tuber ischii around the anus and entirely within the connective tissue between the bulb of the urethra and rectum, or what should be styled the male perineum. The advantage of this is that it gives the widest possible diameter of the outlet, with no hemorrhage to speak of, and easy access to the field of operation. No spurting vessels need be divided, inasmuch as they lay to the outside and in front of the incision. After the integument and tough fascia are divided, the handle of the scalpel may be used to separate the loose tissue between the rectum and urethra, until the fascia covering the levator ani is reached. Division of these structures should be next in order, when the enlarged prostate will make its appearance. The finger is the most convenient instrument in the operation, and should be freely used in opening up the way and separating the gland. At this juncture the prostate may be seized with a pair of vulsellum forceps and pulled



through the incision. If the space be not large enough, the lobes may be removed separately. With a knowledge of the anatomy of the part but little difficulty is encountered in their removal. The step to be guarded is the introduction of a steel sound in the bladder after or during the operation. Puncture of the urethra is an accident very likely to happen, on account that the urethra is loosened up and is very thin. With ordinary care this need not occur. A curved steel sound in the bladder is an aid during the excision. It keeps the base of the bladder from ascending while the gland is being separated.

No operation can be more simple than this, and none can be more important. It promises an easy removal of the prostate, and but slight risk to the patient.

My case was operated on in the way described, and the operation was successful. I found no difficulties to overcome, and can specially recommend this proceeding.

68 West Tuscarawas Street, May 10, 1892.

The Rational Treatment of Pneumonia.—Dr. Reed (*Therapeutic Gazette*, March and April, 1892), from a long and very complete statistical and clinical report on the treatment of pneumonia, urges the justice of the following conclusions: 1. That water locally applied—either as wet pack or baths—is the most efficient single therapeutic measure in acute pneumonia. 2. That veratrum viride or aconite can accomplish more than any other single drug in the first stage, and that the same is true of digitalis in the second stage. 3. That a combination of one of these cardiac sedatives with opium and diaphoretics, affords not only a safe but a highly successful internal treatment for the first stage of acute pneumonia, being capable of aborting the disease when its administration is begun near the onset, and repeated at short intervals day and night. 4. That venesection, though most efficient in sthenic pneumonia, and, if judiciously used, much more successful than any merely expectant method, is no longer an indispensable resource, since other remedies have been found to accomplish the same results more surely and more pleasantly.

THE RELATION OF AURAL AND NASAL AFFECTIONS, BASED ON ONE THOUSAND CASES OF OTITIS MEDIA.[1]

By R. E. SWINBURNE, M.D.,

SURGEON TO THE HARLEM EYE, EAR, AND THROAT INFIRMARY, NEW YORK.

In presenting a paper on a topic that has been discussed ever since otology was deemed worthy of serious consideration, it can hardly be expected or understood that I will present wholly new ideas or views, but rather consider old views in the light of later clinical experience, with the hope that it may result in a better understanding of the various and frequently mixed conditions found here, and consequently in better therapeutic results. This paper is based on the last 1,000 cases of middle-ear disease treated at the Harlem Eye, Ear, and Throat Infirmary, prior to April 1, 1892. They were examined and the diagnosis made in each case by myself or assistants, with no other idea than to keep a correct record of the work done, and without expectation of publishing them, until our chairman invited me to contribute a paper. It was my fortune to begin the study of ear and throat diseases at about the same time, in different institutions, and as my knowledge of them increased, the necessity for treating them together became more and more apparent; but as it was the practice in the older institutions, then as now, to treat them separately, it seemed impossible to carry out that view under existing circumstances, and was one of the reasons for establishing another special institution.

During the ten years since the Harlem Infirmary was opened, the rule has been adhered to of examining the nasal cavities and the naso-pharyngeal space, and treating the pathological conditions found there in every patient suffering from middle-ear disease, with the same care as was exercised in the examination of the ear and the treatment of its pathological conditions. The ear diseases consisted of

Acute catarrhal otitis	64	
Subacute catarrhal otitis	99	
Chronic catarrhal otitis	440—	603
Acute purulent otitis media	136	
Chronic purulent otitis media	230	
Chronic purulent otitis media with aural polypi	31—	397
Total		1,000

The nasal affections accompanying or causing these were:

Acute rhinitis	84	
Subacute rhinitis	33	
Chronic rhinitis	374	
Hypertrophic rhinitis	253	
Atrophic rhinitis	27—	771
Adenoid vegetations	27	
Hypertrophied tonsils	27	
Hypertrophied tonsils and adenoid vegetations	5	
Nasal polypi	8	
Deformed nasal septi	76—	143
Scarlet fever	23	
Measles	11	
Diphtheria	3—	37
Sea-bathing		2
Unaccounted for		47
Total		1,000

These tables show that in this particular 1,000 cases there were pathological conditions of the nasal and pharyngeal membrane to account for the aural trouble in ninety five per cent. Of these, seventy-seven per cent. were of the various forms of rhinitis, 14.3 per cent. had deviations of septum, polypi, vegetations, and enlarged tonsils, and 3.7 per cent. could be attributed to the throat complications of the exanthemata, leaving a balance of 4.7 per cent. in which the cause was not accounted for by our records. Some of these, however, were in children too young to permit of a satisfactory rhinoscopic examination being made, and the aural symptoms had existed so long that the parents could not remember whether or not they had been preceded or accompanied in their acute stages by nasal troubles; it is, however, probable the origin of some of these would have been satisfactorily explained had it been possible to obtain their early histories.

The development of inflammations of the tympanum from nasal and pharyngeal affections has been explained in three ways: 1, By direct extension of the inflammatory process by continuity of tissue; 2, from rarefaction of air in the post-nasal space and tympanum during inspiration, due to nasal stenosis; and 3, from obstruction of the mouths of the Eustachian tubes by adenoid vegetations. My own belief is that it is always due to the first cause, and never to the other two.

Reference to the table of throat and nasal affections, shows there were 518 cases of rhinitis, exclusive of the hypertrophic form, and if we add those resulting from scarlet fever, measles, and diphtheria, we have a total of 555—over fifty-eight per cent.—in which the result could have been produced only by extension, and also include 27 cases of atrophic rhinitis; quite as large a proportion, I think, as would be found in a similar number of nasal affections occurring independently of aural complications.

In my observations of these cases an acute otitis media, either catarrhal or purulent, rarely occurs without an acute catarrhal inflammation involving the whole upper air-tract, beginning usually a few days before the aural affection. A coryza resulting in acute otitis media may attack an otherwise healthy membrane, but more commonly there is a chronic inflammation or an hypertrophic condition that renders it much more susceptible to acute attacks.

In treating patients for nasal affections, who do not complain of their ears, if inquiry be made as to aural symptoms, they will, in quite a percentage of cases, promptly reply, "Oh, yes, when I catch cold I am quite deaf, or have ringing of the ears, or both, and a test will show defective hearing, slight though it may be, and inflation will demonstrate more or less obstruction of the Eustachian tubes. In fact, inflation of these cases by Valsalva's method is generally impossible, and frequently difficult by Politzer's.

As has been stated by Bosworth,[1] there is an absence of "catarrhal inflammation involving the membrane lining the Eustachian orifice, as evidenced by redness, swelling, and hypersecretion," and of the drumheads also, in many cases with chronic catarrhal and hypertrophic conditions of the pharynx and ear; but it is also true that in acute otitis media these evidences of an active inflammation of the Eustachian orifices are rarely absent. The aural symptoms are so much more distressing than those referable to the nose, in all acute inflammations of their lining membrane, that patients at once apply to an aurist rather than to a laryngologist; therefore the latter does not have the opportunity of making rhinoscopic examinations in such cases as frequently as the former.

In the list of nasal affections there were hypertrophic rhinitis, 253; vegetations, 32; deformities of the septum, 76; and polypi, 8; making a total of 369, in which there was nasal stenosis varying from the slightest interference with free nasal respiration to almost complete occlusion of the nasal passages, and necessitating mouth-breathing at all times. But, as this is not much more than one-third of the cases of nasal diseases we are considering, it becomes, for that reason alone, at least a minor factor, and if we inquire further into the nature of the different pathological conditions causing nasal stenosis, we arrive finally at the fact that nearly all of them are themselves the products of frequent and long-continued inflammations, and are usually accompanied by more or less general catarrhal inflammation of the upper air-passages. In speaking of the etiology of vegetations Bosworth says:[2] "The cause of these growths, then, is simply a

[1] Read before the Section on Ophthalmology and Otology of the New York Academy of Medicine, April 18, 1892.

[1] Diseases of the Throat and Nose, p. 131.

[2] Op. cit., p. 541.

tendency to hypertrophy as the result of inflammatory changes which characterize the lining membrane of the air-passages and their appendages, under the stimulus of repeated colds." In my judgment, that is a very clear and concise statement of the etiology of adenoid vegetations, and applies with equal force to the etiology of hypertrophic rhinitis.

Nasal polypi are never found in an otherwise healthy nose, and occur so infrequently in aural disease, as to be of relatively little consequence to aurists.

I have seen many patients with adenoid vegetations and hypertrophic rhinitis who have presented themselves with acute catarrhal or purulent otitis media, and furnished histories of repeated perforations or acute catarrhal otitis during attacks of acute rhinitis, with a partial or complete disappearance of the aural trouble after the acute inflammation of the nasal mucous membrane had subsided, only to reappear on the next exposure, resulting, finally, however, in considerable damage to or total loss of the ear as an organ of hearing in the vast majority of instances. If the chronic ear affections accompanying vegetations are due to the stenosis, rather than to direct extension of the inflammatory process, how are the acute attacks to be explained? Then, again, it is not rare to find better hearing on the side of greater obstruction of the Eustachian tube, indicating plainly that the damage to the ear is the result of inflammation in the tympanum, rather than to rarefaction of air in the naso-pharynx. Deviations and exostoses of the nasal septum are perhaps not so easily explained as to their origin, although the cause is traumatic in all cases in which it can be ascertained. That they interfere with respiration, and consequently the circulation, and eventually lead to chronic inflammation and pathological changes of the nasal mucous membrane, that render it susceptible to acute inflammatory attacks, frequently involving the lining of the Eustachian tubes and tympanum, does not admit of a doubt; but that the stenosis they cause has any direct action in producing the aural complications, I do not believe. Furthermore, it seems to me incredible that patients would make the physical effort necessary to rarefy the air in the naso-pharynx, and produce the series of results mentioned by continuing to breathe through the nose in these cases, when free respiration can be had by simply opening the mouth.

I do not wish to be understood as saying or implying that nasal stenosis is a matter of little or no consequence, but, on the contrary, regard it of serious importance aside from its relation to aural affections. As to the third cause, I can only say that in none of these cases were the mouths of the Eustachian tubes obstructed by vegetations, nor have I seen such extreme development of them, except in very rare instances; although constantly seeing and operating for their removal in dispensary and private practice, both in connection with and independent of affections of the tympanum.

In the table of throat affections, the term rhinitis has been employed in preference to pharyngitis, or post-nasal catarrh, generally used in the older works on throat diseases, and still retained largely in works treating of otology, for the reason that rhinologists have, during the past fifteen years, come to appreciate the fact that this particular part of the membrane is most liable to acute inflammations, and is the most frequent seat of the more important pathological changes found in the upper air-passages, although the whole membrane is always necessarily involved. That this should be so will at once become apparent, if we consider that, in addition to olfaction, the function of the nose is to warm and filter the air in its passage to the lungs; and that this may be successfully accomplished the turbinated bones have been provided, and their extensive surfaces covered with a mucous membrane richly supplied with relatively large blood vessels, thus furnishing, with the constant exposure to rapid, frequent, and extreme changes of temperature, all the elements necessary to bring about inflammatory attacks. Theoretically, and for the purpose of classification, it is well enough to apply different names to the affections of the different parts; still we must admit that the mucous membrane lining the nasal chambers, the naso-pharynx, and the accessory cavities, including the tympanum, is practically one membrane, notwithstanding the slight histological variations of its different parts, and that inflammations, or pathological conditions of its most exposed parts, are liable to, and frequently do, extend to its more remote and less exposed parts. That nearly all affections of the tympanum are produced in this manner, by the extension of inflammatory processes, beginning in the soft tissues covering the turbinated bones, extending not to other tissues, but along the same membrane to the middle-ear, is to me perfectly plain; therefore we must recognize that the tympanum is anatomically, physiologically, pathologically, and therapeutically inseparable from, and an important part of, the upper-air passages, notwithstanding its chief function is intimately connected with audition.

The origin of the acute forms of otitis media in this manner is so universal, that the aurist, who regularly and carefully inspects the nasal cavities and naso pharynx in these cases with the aid of the modern instruments, skill, and knowledge of the rhinologist of to-day, will rarely find a so called primary case. This, together with the further fact that in the cases of chronic aural catarrh, representing at least one-third of all the ear cases an aurist sees, and including those hypertrophic processes of the lining of the tympanum with anchylosis of the ossicles, and variously designated as adhesive, proliferous, etc., are rarely found, except in patients who have not also much greater pathological changes in the nose and naso-pharynx, as demonstrated by actual inspection of the parts—renders it, certainly in the absence of any other reasonable explanation, more than probable that a mild, or possibly a more severe, otitis occurs during an acute rhinitis, is prolonged by the indefinite duration of the nasal inflammation, until a certain amount of permanent change has taken place in the tympanum. This process is repeated with successive coryzas, until it produces the conditions we are familiar with in those many incurable cases that almost become the bane of an aurist's practice.

Politzer expresses a similar view and says further:[1] "Inspection of the posterior pharyngeal wall, lying behind the cavity of the mouth, frequently gives information as to the condition of the mucous membrane of the superior pharynx, from the changes which can be there observed. . . . Often, however, without the slightest visible change of the posterior pharyngeal wall, far-advanced affections of the mucous membrane of the superior naso-pharynx may be found."

On the other hand, Roosa says: "The rhinoscope will be found a valuable assistant in a few cases for an exact diagnosis of affections of the naso-pharyngeal space. As a matter of fact, however, very few of us who treat a great deal of aural disease make much use of the rhinoscope. It is only in exceptional cases that we find its revelations compensate for the time employed."[2]

I distinctly remember being in conversation with two well-known members of this Section, when one of the gentlemen remarked that he intended to learn to make rhinoscopic examinations, to which the other promptly replied, That is too difficult. I think this illustrates a rather general feeling among aurists, and, while the difficulties are real to those not skilled in making rhinoscopic examinations, they can be readily overcome by the experience and practice afforded by a few months' daily attendance at any of the large clinics for throat diseases in our midst; and after the necessary practice has been had, without which the ability to make examinations quickly, yet thoroughly, and a practical knowledge of the pathological conditions existing here cannot be acquired, no

[1] Diseases of the Ear, pp. 303 and 310.
[2] Treatise on the Diseases of the Ear, Seventh Edition, p. 371.

one will complain of the time required, or a lack of revelations that are to otitis media as cause and effect.

Among the affections mentioned in the table are nearly all the forms and degrees of diseases the nasal cavities and naso-pharynx are liable to, and include a greater variety of pathological conditions than occur in the various forms of otitis media; therefore, in view of the fact that nasal diseases were associated with ninety five per cent. of all the ear cases, it is of the utmost importance to make anterior and posterior rhinoscopic examinations and treat pathological conditions existing there, in all patients suffering from diseases of the tympanum, with the same care and skill as we exercise in the examination and treatment of the aural affection. By so doing the otitis will not only be of shorter duration, but will result in less permanent damage to the ear, and the removal of the nasal affection will render the patient less liable to the acute inflammations of the lining membrane of the ear that finally result in serious permanent damage.

Looking at the practice in this city, we find the college professorships of otology and of laryngology, or rhinology, occupied by gentlemen quite universally recognized as authorities in their respective departments, but not in both. Again, in the eye and ear institutions, although the necessity of treating the throat has in a limited way been recognized by the establishment of throat departments entirely separate from the ear departments, I fail to find among the list of surgeons the names of gentlemen who are known as both aurists and rhinologists.

In this Academy we rarely meet the members of the Section on Laryngology in this Section, nor do the members of this Section frequent the meetings of the throat specialists. Superficially, this might be construed as evidence that the views just expressed are erroneous, but further consideration will entirely dispel any such idea.

The study of otology was begun first, probably because of the more serious result following ear disease, and was well advanced when throat specialists began their active careers; consequently our older institutions for eye and ear diseases were already in operation, and the older oculists and aurists now most prominent in their management, were busy practitioners with too much to do, both in hospital and private practice, to incline them to enter new fields.

While the development of otology and rhinology, as well as other special branches, is wholly due to the researches of specialists in their respective departments, no one, I think, appreciates or regrets more, or perhaps as much, that the pursuit of a specialty tends to limit the field of vision or narrow the man, than those of us who have chosen to limit the practice of medicine to certain branches. We should therefore broaden our field and attempt to get out of old ruts, whenever it can be done consistently, and especially, as in this case, advantageously both to ourselves and those who place themselves in our hands. Those who do so will not only extend their field of practice, but as aurists will have the satisfaction of curing ear cases promptly that otherwise would be indefinitely prolonged and suffer greater permanent damage. They will also do much toward establishing their reputations by removing the cause of frequent and distressing attacks of acute otitis media in patients that have passed through the hands of other, and sometimes better-known, aurists, who do not make careful rhinoscopic examinations in all of these cases, and consequently wholly overlook and fail to remove the cause.

That "this is a condition and not a theory that confronts us," is certainly proven by the list of nasal and pharyngeal affections in the above table, and will be confirmed by practitioners possessed of a thorough knowledge of the diseases of both ear and nose. During the last few years remarkable progress has been made by rhinologists in the knowledge and treatment of those nasal affections we as aurists are directly interested in, but possibly have overlooked.

The nomenclature has been somewhat changed as a better understanding of pathological conditions has been acquired. Light, spring, self-retaining specula that can be quickly introduced, have taken the place of heavy, cumbersome instruments requiring the use of one hand to retain in position, or the turning of a screw to expand the blades, that are as great an improvement as the modern ear specula are over Kramer's bi valvular instrument.

The recognition of the necessity of surgical interference in those conditions producing nasal stenosis has necessarily resulted largely in the abandonment of the use of washes and astringents; but that they are of very great value in the treatment of inflammations here as elsewhere, cannot be doubted, especially in the purulent rhinitis of children too young to remove the secretions by their own efforts. That there is danger of fluids reaching the tympanum and causing acute inflammation there, is, of course, settled; but the danger depends largely on how free the Eustachian tubes are, and such accidents would be much more frequent if they were not generally obstructed in patients suffering from rhinitis. By ascertaining the condition of these tubes, unpleasant results may frequently be avoided.

Nothing has been said about hypertrophied tonsils more than to mention their presence in thirty-two cases, because they do not seem to me to cause otitis, except as a part of a general catarrhal condition of the upper air-passages that renders them liable to acute inflammations. As such, however, they are important, and if there is any considerable enlargement, they should be removed.

The three hundred and sixty-four cases of nasal stenosis represent conditions to be viewed from a surgical stand-point only, and emphasize how necessary it is that every aurist should be a rhinologist; for otherwise, how will it be possible to either diagnose or treat successfully so large a variety and number of affections occurring so constantly in routine practice? Adenoid vegetations should be removed without delay, but, more important still, because of their greater frequency are those various conditions of the turbinated bodies classed under the head of hypertrophic rhinitis, and also generally found with vegetations and deformities of the septum. The introduction of convenient snares, armed with piano-wire, has made the removal of polypi and turbinated hypertrophies a rather simple procedure, and now the use of strong solutions of cocaine, together with saws, chisels, drills, etc., have brought bony obstructions of the septum easily within the domain of office surgery that every aurist should be ever ready to meet, and treat intelligently and successfully.

128 West 126th Street.

Treatment of Appendicitis.—Dr. Senn's conclusions are these, viz.: 1. All cases of catarrhal and ulcerative appendicitis should be treated by laparotomy and excision of the appendix as soon as the lesion can be recognized. 2. Excision of the appendix in cases of simple, uncomplicated appendicitis is one of the easiest and safest of all intra-abdominal operations. 3. Excisions of the appendix in cases of appendicitis before perforation has occurred, is both a curative and prophylactic measure. 4. The most constant and reliable symptoms indicating the existence of appendicitis are recurring pains and circumscribed tenderness in the region of the appendix. 5. All operations should be done through a straight incision; parallel to and directly over the cæcum. 6. The stump after excision of the appendix should be carefully disinfected, iodoformized, and covered with peritoneum by suturing the serous surface of the cæcum on each side over it with a number of Lembert stitches. 7. The abdominal incision should be closed by two rows of sutures, the first embracing the peritoneum, and the second the remaining structures of the margins of the wound. 8. Drainage in such cases is unnecessary and should be dispensed with.—*Medical Progress*, March, 1892.

CREOSOTE IN THE TREATMENT OF PULMONARY TUBERCULOSIS.[1]

By A. L. HALL, M.D.,

FAIR HAVEN, N. Y.

That among the numerous remedies which have found favor in the last few years in the treatment of pulmonary tuberculosis, creosote stands pre-eminent, few will deny.

This verdict has been reached after a careful comparison of the results attained by the use of this agent with those secured by the other various remedies lately employed in the treatment of the different stages of pulmonary tuberculosis, as observed in the public and private practice of some of the most intelligent members of our profession in this country and in Europe.

Although slow at first in finding recognition, creosote has steadily grown in professional favor, and to-day the confidence it has inspired among those who have given it a thorough trial is fittingly expressed by Dr. Beverley Robinson[2] in his recent article upon this subject, in which he says: "Judged fairly in comparison with other drugs, I have come to regard creosote as the most valuable medicinal agent we have at the present time for the treatment of pulmonary tuberculosis."

Confronted by such evidence regarding the notable results claimed to have been obtained by the use of creosote in the treatment of this disease, we are naturally strongly led to inquire more fully into their nature.

A search into the literature of this subject shows that during the first and second stages of pulmonary tuberculosis the following results, with few exceptions, will slowly appear after a considerable time has elapsed during which the treatment has been faithfully maintained: Digestion markedly improves, the appetite is increased, the bowels are relieved of irritating ingesta, and the diarrhœa and constipation are overcome. As a natural result the nutrition is notably improved, the bodily weight increases from two to twenty pounds, and according to some observers the gain amounts to fifty pounds. With the increase in bodily weight there is a corresponding gain in the physical strength, and the disposition becomes more cheerful. The patient takes new hope and evinces a desire for bodily and mental exercise. Cough and expectoration lessen and finally cease. The fever decreases and the temperature is gradually brought to the normal point. Night-sweats diminish and soon disappear. The respiration becomes fuller and deeper, and the physical signs are gradually abated. Cardiac irritability is controlled, and in time the pulse regains its normal character. In fact, there is a very marked improvement in all of the physical signs and symptoms.

In many instances where benefit has not followed the use of cod-liver oil, the hypophosphites, and other approved remedies, very gratifying results have promptly followed the use of creosote.

While it is not claimed for this treatment that it has the power to arrest or cure the advanced forms of pulmonary tuberculosis, still it exerts in these cases a marked beneficial effect in palliating the symptoms and in retarding the progress of the tubercular process.

The dosage and form of administration of creosote vary considerably, depending upon the ability of the patient to bear the remedy, while more hangs upon the faith and courage of the administrator as regards the employment of this agent in medium or large doses. The German authorities favor a daily dosage of one-fourth to one drachm. In this country there is more timidity as regards the employment of large daily dosages, and as a consequence the results have not been so marked with us as with the Germans. This conservatism, however, is fast disappearing, and there are those among us who are giving the larger daily dosages with better results.

From all that has been written upon the subject it strongly appears that those physicians who have employed the larger doses of creosote have obtained better results than those using the smaller amounts.

Dr. Beverley Robinson, who is the pioneer in this country in the use of creosote, prefers small and frequent doses. He commences with doses of one-half to one minim, given three to four times daily, and gradually increases the frequency to every two hours, unless the stomach proves intolerant. He finds that few patients can bear a daily dosage of more than twenty minims, although one of his patients took sixty-four minims daily. His method is a very good one and commends itself on account of its safety, and is always capable of being pushed to the fullest extent compatible with the comfort of the patient.

Some prefer to give creosote in pill form, others in capsules, while there are those who favor various mixtures of this article. The better way is to give it in an alcoholic or vinous mixture. A noted German authority combines it with two parts of tincture of gentian.

Much of the success acquired from the use of this remedy is attributed to the employment of a reliable article, one of absolute purity manufactured from beech-tar.

I have employed the following formula with good results:

R.	Pure beech-tar creosote, Merck's	ʒ j.
	Fl. ext. gentian	ʒ ij.
	Comp. tincture of cardamom	ʒ j.
	Alcohol	ʒ ij.
	Simple sirup q. s. ad.	ʒ viij.
M.	Sig.: One teaspoonful as directed.	

After tolerance is established the quantity of creosote and gentian is gradually increased in the proportion given above.

I have made a prolonged and satisfactory trial of this remedy in a single case of pulmonary tuberculosis, the history and results of which are as follows:

About two and one-half years ago, Mrs. L——, aged thirty, with a family history of tuberculosis, had a severe attack of epidemic influenza with an imperfect recovery, following which her health steadily declined until the last of December, 1891, when she was seen and placed under the creosote treatment. At this time she presented the following symptoms and physical signs of disease: There was well-marked emaciation with greatly impaired muscular power. The cachexia was pronounced, the skin being of a pallid hue, while the veins were distended and of a dark color. The heart was in a very irritable state, and the pulsations, when the patient was quiet, numbered 120 per minute. The respirations were from 24 to 28 per minute, the inspiration being shallow and shortened, while the expiration was prolonged and harshened. There was unusual prominence of the clavicles and the infra-clavicular spaces were depressed, especially upon the left side. There was well-marked dulness over the entire left infra-clavicular region, with fine moist râles and exaggerated vocal fremitus. There was also slight, yet perceptible, dulness over the apices and the right infra-clavicular space. The normal vesicular character of the breathing was absent in these situations, particularly upon the left side, being replaced by the broncho-vesicular and bronchial breathing. There was cough, with moderate expectoration of a thick muco-purulent character. The hectic was well marked, night-sweats were exhausting the patient, and the outlook for the future was very unpromising. In addition to the foregoing symptoms, there was an aggravated form of dyspepsia and some diarrhœa alternating with constipation. She was given one-half drachm of the creosote mixture three times daily, which was soon increased to one drachm four times daily. From this time the amount was steadily increased, and at this date, July 10, 1892, the daily dosage equals fully eighteen minims of pure creosote. There has been no intolerance or discomfort at any time arising from the use of this agent, but, upon the contrary, the effect has

[1] Remarks made at a discussion of this subject at the regular Annual Meeting of the Medical Society of the County of Cayuga, held at Auburn, N. Y., June 9, 1892.

[2] On the Use of Creosote in the Treatment of Pulmonary Phthisis, MEDICAL RECORD, February 27, 1892.

been grateful to the patient and the results have been gratifying beyond expectation.

During the first two months of the treatment there was scarcely any improvement. Afterward, the improvement slowly manifested itself, and at the present time there is a marked change for the better. The nutrition has greatly improved, the bodily weight, which was 92 pounds when first seen, has increased until she now weighs 105 pounds—a net gain in six months of nearly fifteen per cent. of the entire bodily weight at the time the treatment was first instituted. The gain during the last two weeks has been slightly in excess of two pounds. With the increase in weight there has been a corresponding increase in the physical strength, and instead of being confined to the bed the patient is now able to be about the house, and walks and rides frequently in the open air without detriment. In place of depression of mind there is an animating hope of an early recovery. The appetite is improved, the diarrhœa was early arrested, the night-sweats are a thing of the past, the cough is controlled, the cachexia is fast disappearing, and the heart-action is no longer rapid, the pulsations now numbering 84 per minute. The respirations are lessened in frequency and fuller in depth. The dulness is diminished, and the other physical signs are slowly abating.

I have watched with more than ordinary interest the changes the patient has undergone from time to time during the six months I have had the pleasure of treating her. What will be the final outcome of the case, is a prediction that I do not at this time care to make. However, I will venture the opinion that recovery will not be fully and safely completed in less time than three or more years from the time that the treatment was first undertaken. Syphilographers claim that about four years of continuous treatment is required to fully and permanently eradicate the syphilitic taint. If this be true, is it reasonable to presuppose that the tubercular taint can be effectually removed in a shorter time? For my part, I believe not. I am strongly inclined to believe that many cases of tubercular phthisis can be cured when the treatment is faithfully and perseveringly extended over a long period—three to five years—and that, too, by other remedies than creosote.

In conclusion, I desire to state that I am cognizant of the fact that there are a few physicians who have tried creosote in pulmonary tuberculosis, and who claim to have achieved no better results with this agent than they have been able to obtain by the use of tuberculin. So far as I can learn, these observers have had only slight experience with this agent in the treatment of this disease, consequently their assertions are of little value.

I am also aware that, about sixty years ago, creosote was brought to the notice of the profession as a remedy of considerable value in the treatment of pulmonary tuberculosis, and after a short trial in which the results are said to have been good, it fell, as many other valued remedies have fallen, into disuse as a curative agent in the treatment of this disease. Notwithstanding this apparent failure of years gone by, together with the alleged want of success in recent times on the part of a few experimenters with this agent, still I am led to conclude from my slight experience and the large amount of reliable literature upon the subject, that at the present time creosote excels all other therapeutic agents or measures in the treatment of this almost incurable affection, pulmonary tuberculosis.

Prize for Essay on Tuberculosis.—The Congress for the Study of Tuberculosis announces a prize of three thousand francs for the best essay on "The Means of Diagnosticating Latent Tuberculosis before its Appearance or after its Cure." The essay must be written in French and sent to Dr. L. H. Petit, 76 Rue de Seine, Paris, before April 1, 1893. Each memoir should be accompanied with a sealed envelope containing the author's name and address.

THE ROCKY MOUNTAIN REGION FOR CONSUMPTIVES.

By EUGENE M. LITTLEJOHN, M.D.,

HONORARY FELLOW OF THE NORTH CAROLINA STATE MEDICAL SOCIETY, ETC., MONTROSE, COL.

There is no one disease that has occupied the mind of the medical profession for the past year or two as has phthisis pulmonalis. Since the announcement of Professor Koch's discovery, many and varied have been the remedies proposed for the cure of this disease. I don't propose, however, in this paper, to discuss the merits or demerits of any of these new therapeutic measures, or, in fact, any of the old ones either, except that of climate.

It is generally conceded that the consumptive, under any method of treatment, is very greatly benefited by a residence in a suitable climate, and by the proper surroundings in said climate. In fact, with many of the most careful observers this climatic influence is considered more potent for good than any or all the other measures resorted to.

What I shall have to say will be from the stand-point of the patient as well as that of the physician; and the conclusions reached are based entirely on facts as gathered from my own experience and direct observation of others while at these health-resorts. For about three years I have been a consumptive myself, and have been spending my time at the different health-resorts, both East and West. I hope to be able to give some points from this experience that will be useful to many of my professional brethren, who are so often called upon to give advice to the consumptive regarding change of climate, etc. If I had had access to these details at the beginning of my attack, I am sure it would have been of vast benefit to me, and would have prevented my making many mistakes that have cost me dearly in many ways. It is my desire to allow others to profit by my experience that impels me to write this article.

To begin: I will state that the section of country possessing the most beneficial climate, in my opinion, for consumptives generally (unless they have passed the stage where permanent improvement is possible), is what I may call the Rocky Mountain Region. I mean by this the elevated section of country amid and on both sides of the Rocky Mountains, extending from El Paso, Tex., or the southern line of New Mexico, north through the whole of New Mexico, Colorado and into Wyoming. In making this statement I must say that I have not arrived at this conclusion by studying the meteorological reports of the different sections, or by other theoretical means, but entirely by results that I have observed. For instance, the convincing proofs, to me, of what this climate will do for consumptives are the "living examples" that can be seen all over this section. I don't know of a town in all this district that does not have several inhabitants, and often many, who came to this country as consumptives, and who are now enjoying good health, and in many cases robust health. The number of such persons one meets is so large that it is quite convincing. In many instances they are physicians, and other cases that are entirely authentic. Many of these cases were in the advanced stages when they came.

If we go to analyze the climate itself, it has many objectionable and disagreeable features; but I think it does more for the consumptive than other places with which I am acquainted. I don't mean to argue that there are no good climates for consumptives in the East and elsewhere. There are noted resorts in the East, at which I have been myself, and where the climate is very fine, and so much better than the place from which the patient usually comes that most patients seem to improve, at least for a time, and some do recover. But I have not been able to observe the proportion of recoveries which take place in the section above mentioned, although I have had opportunities of observing. The fact is, occasional recoveries do take place almost everywhere; but I can recall very few permanent cures that have occurred

east of the Rocky Mountain district—very few at least in proportion to the number of cases. Some may argue that more consumptives go to this section than to any other. This may be true, but this is a big country, and they are scattered all over it, from El Paso to Wyoming, an area of nearly one thousand miles in length and several hundred miles wide in many places.

It often happens that a patient is sent by his physician "to Colorado" or "to New Mexico." The patient in the first instance lands at Denver, Pueblo, or Colorado Springs. He remains there for a very limited time, and decides that Colorado does not agree with him, as he can see no great improvement He is probably a little homesick anyway by this time, so he pulls out for home, and it goes on record that this patient was not benefited by Colorado

If he is sent to New Mexico, the same thing may happen at Las Vegas, Albuquerque, or Santa Fé. Now, in the first place, anyone who has seen much of these patients in this section has noticed that it is the exception for a consumptive to receive much real benefit before he has been here about six months, though, of course, the exception may occur. In many instances the patient comes expecting to accomplish his object and return home within six months, and often earlier. This, of course, is great folly, even if he does greatly improve. If a patient should come to one of these towns and find it did not agree with him, he should try elsewhere.

As already stated, this is a great section of country and necessarily contains many variations in climate as well as altitude. It is often the case that one part of Colorado will not suit a patient, while some other place, either higher or lower, as the case may be, seems to suit him exactly. Yet it would be rather indefinite to tell a patient to go to Colorado or to New Mexico and hunt around until he finds a place to suit him, and it might consume much valuable time as well as money. So I will mention some of the more important towns, each representing a certain section, and will give the leading features of that town or section. This, I hope, will enable those unacquainted with these localities to select the place best suited to any individual case, and in case the first place does not suit, he can select the next place most likely to suit him which can be reached with the least amount of travel. Having a knowledge of these conditions at different places will save much time and expense in travelling around, which with many patients is an important matter.

Beginning at the southern end of this district, there is El Paso, Tex., which is on the border of Texas, New Mexico, and Old Mexico. This little city has an altitude of 3,717 feet and a most desirable winter climate. Very good accommodations are to be had, there being many hotels and private boarding-houses.

Following the Rio Grande River and the Atchison, Topeka & Santa Fé Railroad north forty miles, brings us to Las Cruces, N. M., situated in the beautiful Misilla Valley. This climate is much the same as that of El Paso, but I think has some advantages over the latter; the accommodations, however, are much inferior to those of El Paso, and its location is slightly higher. It is my opinion that as winter-resorts these places have no superior. The climate here being milder and the altitude lower than in any other part of the Rocky Mountain section, makes it especially suitable for the more advanced cases, and as a starting point in winter for most cases. If it is thought at any time that a higher altitude is needed, it can be had very conveniently by going north via the Santa Fé Railroad, which has a gradual ascent all the way north to the Colorado line, so that any elevation desired, between that of El Paso and seven or eight thousand feet, can be tried in succession if desired. And this course is always convenient to patients when summer opens and it gets too warm here for comfort.

In speaking of these places as winter-resorts it is meant that the climate is desirable for fall, winter, and spring. It is only during the heat of summer that it becomes unpleasantly warm—this applies to all places spoken of here as winter-resorts—so that many adopt the plan of remaining all the year at Las Cruces, for instance, until the weather gets too warm, and then they go camping in large parties to the Organ Mountains, which are only twenty miles distant, and a pleasant drive. This, again, is desirable for more advanced cases, since the benefits of the mountains for summer can be had without reaching the high altitudes that are found in the mountains farther north.

Following the railroad north, as before stated, there is a gradual ascent. I will mention only a few of the more important places. Socorro is about one hundred and thirty-five miles north of Las Cruces, and is a very pleasant place, especially for the winter. Its altitude is about four thousand six hundred feet. About seventy five miles north of this place is the commercial centre of the Territory—Albuquerque. Here almost every kind of accommodation can be had, and the climate is a particularly good one for winter. The elevation is medium (4,949 feet), and is well adapted to many cases. Proceeding still farther north, about eighty miles, we come to the Territory's ancient capital—Santa Fé. We have now reached an elevated section of country; this little city having an altitude of 7,046 feet, is, therefore, more desirable as a summer-resort, although many cases, especially early ones, or those who have become accustomed to high altitudes, do better at a place like Santa Fé, even in winter, with its cold, bracing air. Good accommodations are to be had here.

About sixty miles farther northeast is Las Vegas, which is quite noted as a resort. Its altitude is 6,398 feet, and what has been said about Santa Fé may properly be said also of this place. Six miles out from Las Vegas, connected by rail, are the famous Las Vegas Hot Springs. Here is to be found one of the handsomest and best appointed hotels in the whole country. It is built of stone and owned and operated by the Santa Fé Railroad Company.

About one hundred miles north, near the Colorado line, is Raton, N. M., which is a very desirable point for those requiring an altitude of 6,636 feet. After crossing the Colorado line the railroad descends again, so that when the next town of importance—Trinidad, Col.—is reached, we find an elevation of only 5,944 feet. This is a small city of some importance, and its climate is well suited to many cases. Descending still, ninety miles north, brings us to Pueblo, the city having about the lowest altitude of all the places of importance in Colorado—so far as I know—4,669 feet. Now I consider Pueblo the best starting-point for Colorado, as El Paso or Las Cruces is for New Mexico. And the northern New Mexico points can also be conveniently reached from here. When a patient starts west in the late spring or in summer, I think it is better to go to Pueblo than to southern New Mexico; and with the patient not too far advanced, this course is often preferable even in winter or fall. As a winter climate that of Pueblo is one of the best in Colorado, and this place offers excellent accommodations.

Colorado Springs is forty-five miles north, and has an altitude of about six thousand feet. This is one of the loveliest little cities to be found anywhere. It is strictly a residence city and a resort, containing many first-class hotels and boarding-houses. It is rather an expensive place to live in, however. This is an all-year resort, but is especially pleasant in summer.

Five miles from here is Manitou Springs, which is the Saratoga of the West. It has elegant hotels, but is more of a fashionable pleasure-resort than a resort for consumptives.

Denver is only seventy-five miles north of here. Its altitude is 5,196 feet, and many find it especially desirable to spend the winter here. For those who are able to do business, it offers more opportunities than other places. The climate is excellent, though somewhat colder in

winter than that of Pueblo. Denver is an elegant, modern, and growing city, and is a most pleasant place for those who have recovered sufficiently to do business to make their home; or for those persons whose health has not been sufficiently impaired to necessitate their giving up business entirely.

There are many smaller towns north and west of here, both in Colorado and in Wyoming, offering many advantages in different directions. I will not undertake to enumerate them, as the person who goes to Denver can learn here all the particulars desired.

From Pueblo, about forty miles west, and up the Arkansas River, is the town of Cañon City, which I must not pass without mention. It is a beautiful town, of about three thousand inhabitants, and, in my opinion, offers more advantages as an all year resort than any other place here mentioned. Its altitude is 5,344 feet, which is a good medium one. According to the reports of the United States Signal Service it has the mildest winter climate in Colorado. This is due largely to its sheltered location, the surrounding mountains breaking off the cold winds. It is reached from Pueblo via either the Santa Fé or the Denver & Rio Grande Railroads.

Proceeding west via the last-named railroad, across the continental divide, we come to some sections of country offering many varieties of climate and altitude. The most important of these suitable for a winter residence are Montrose, Grand Junction, and Glenwood Springs, with altitudes respectively of 5,793, 4,583, and 5,200 feet. The first and last named places are also particularly valued as all-year resorts. They are all very thriving towns, with good hotels, etc., and are located in the fruit growing section of the Western Slope. Each of these towns is surrounded by fine agricultural communities. The principal reason that these towns of the Western Slope are not more frequented by consumptives from the East is, that in order to reach them it requires a journey by rail over very high mountain passes—Marshall Pass, for instance, being 10,852 feet. For this reason many are afraid to attempt the trip. But I think those with early cases need have no fear of it after having become accustomed to a moderately high altitude. It is often the nervous fear of the person that causes most of the trouble experienced in crossing these high elevations. The most of the sections mentioned are the ones considered most suitable for winter and all-year resorts; but as suggested in speaking of Santa Fé and Las Vegas, many of the more vigorous patients do better, even in winter, at points with an elevation of 7,000 or 8,000 feet, and some few even higher (this is of course exceptional). Many towns of this class are to be found here in Colorado, as, for instance, Salida, Aspen, Ouray, Gunnison, Durango, etc.

Then, as summer opens, it is desirable for those who are in the larger towns or warmer sections to get out to the mountains. Colorado is full of these summer-resorts, and many of the most approved can be reached by the various lines of the Denver & Rio Grande Railroad. I will not speak separately of them. The railroads issue handbooks giving full information about them. I will say that the most of them vary in altitude from six thousand to over eight thousand feet. Many of them possess excellent facilities for hunting and fishing. It is very desirable to get patients out in camping parties where fishing or hunting can be pursued. Often wonderful improvement is noticed after one of these trips of "roughing it." The person who went out looking so delicate comes back bronzed and tough. The various towns above mentioned are named just as representatives of certain localities, and, of course, it is not meant that they are superior to many other places not spoken of here.

The question now arises, What is the patient to do after he arrives at a suitable place—what kind of life is he to lead? This is an important question which puzzles many. Often his physician has simply told him to "go to Colorado," or "to New Mexico," and take all the exercise he can, and live out of doors. This kind of advice has often injured the patient. He over-exercises, regardless of the fever it is causing, and therefore grows worse constantly. Still, I don't approve of starting a patient with a thermometer, as he will then be watching his temperature continually and worrying over it. The most favorable cases, I find, have some rise of temperature in the evening, if they are exercising at all. I think it best not to tell a patient that he is subject to fever (he often does not know it), but to explain to him not to exercise enough to cause a dull headache, heavy, dragging sensation in the limbs, etc. These sensations are sure to express themselves if he is having fever enough to be harmful, that is, if it goes over 100° F. Others go to the other extreme, and tell them not to take enough exercise to cause any fatigue. I don't think it possible for a consumptive to take enough exercise to be of any benefit without producing some fatigue. And I know from my own experience that there is a great difference between the feeling of natural fatigue and the dragging sensation caused by fever.

I am convinced that the best thing for the consumptive to do, as early as he can after arriving, is to get out of town. Even if he is able to stop at the best hotel in the city, there are many reasons why he would do better to get out into the country, if he is in condition. The most objectionable features of this climate, all over, are the winds and the dust, especially in the spring. In town, where there is constant travel on the streets, there is no chance to avoid the dust, and the only place to escape it is in the country, where there is usually very little. Of course the amount of wind depends largely upon how well the place is sheltered by mountains. Another reason for getting out is, that a person in town is very apt to continue the same habits of living that he was accustomed to at home, or, at least, he will lead a very aimless life, with nothing to do, and nothing to think of but his complaint. He is told to live out of doors, but he cannot walk far without tiring; the same with riding; and if it is winter he finds it too cold to sit out. So let him get board at some nice ranch (all farms are called ranches in this country). It need not be far from town. Let him make up his mind to take an interest in what is going on, and as he feels like it, help to attend to the poultry or the horses; or, if he is able, assist in riding after the cows, etc. There are many little things which may occupy a person on a farm, and which will keep him out of doors and at the same time afford him occupation and amusement. This is surely much better than to be lounging around, taking exercise—when it is taken—with no other motive than to be exercising. Then the amount of exercise can be regulated to suit the case or condition; the dust is avoided and the purest air is breathed. Nearly all these towns are surrounded by suitable ranches, whose proprietors are often willing to take one or two or more boarders. If the ordinary ranch fare is not suited to his digestive powers, arrangements can be made for any extras required, and if the place is not too far from town, he can amuse himself riding or driving in for his "extras" or for his mail. But if he gains, as many do, after this plan of treatment, he will soon get so that he can digest whatever is put before him.

As already suggested, it is also an excellent plan, for those who are vigorous enough to stand it, to go out to the mountains in summer, camping where there is good fishing and hunting. If a camping party cannot be organized, then there is good sport to be had at many of these summer-resorts, especially in remote and newly opened mountain districts, on or near the new lines of railroad.

One of the most important, and often difficult, tasks the physician has to perform in these cases is to impress it upon the mind of the patient that he must remain permanently in this country. Even if it has resulted in a perfect cure, it is most hazardous for him to return home, unless for a very short visit, and during a favorable time

of the year. While admitting that a person may regain his health and return home without ever having a return of the disease, yet the chances are so much in favor of the opposite result that no person can afford to run the risk. This has been demonstrated only too often. After a person has regained his health it is not necessary to be confined to any one special place, and he need have no trouble in finding a place in this great section where it will be both pleasant and profitable to live. If he prefers a residence in a city, he is indeed hard to please if Denver, Pueblo, or some of the smaller cities of the district do not satisfy him. Of course no one intends to convey the idea that this climate will cure, or even relieve, all cases, and those cases which have failed to be benefited, after a fair trial here, of course should go elsewhere. But, as stated before, marked improvement must not be looked for too soon, or until several different varieties of climate have been tried, if need be.

The last, "but by no means least," question I wish to touch on, is the advisability of sending young people, who have marked hereditary or other predisposition to lung disease, to this elevated district to live, before the disease has developed. This may seem to some people as going to an extreme, but I look upon it as one of the most pressing duties of a physician, when he sees among his clients a young man or girl, who he knows has inherited this tendency to consumption, and whose general make-up shows how fully this tendency is possessed (it is not difficult to see), I say it is the sacred duty of the family physician to advise this young person, before the disease takes hold of him, to change his residence to a suitable climate, where it has been proven that the chances of developing phthisis are reduced at least ten to one, and I think more. The person and family should be given to understand the case as it is. There are few physicians who cannot think of such a person among the families under their care—a young person, who, under the existing conditions, he knows does not have one chance in five of escaping phthisis before passing the dangerous age. When one of these young persons begins to lose flesh and feel tired, or becomes subject to very frequent "colds on the chest," then it is especially important to send him at once to the above section, before the disease has progressed sufficiently to be recognized by physical examination. Fortunately a great many have seen the wisdom of this course, and many are the lives that have been saved thereby.

Many people claim that they are not able, financially, to take advantage of this course, but when they consider what is involved, no sacrifice should be considered too great. In the case of a boy, he had better come here without a cent than to run such a risk. If he has come early enough, he can, at least, work for a living, and there is no country affording better rewards for industry and offering better chances for advancement than this.

Cannabis Indica in the Painful Diseases of Women.—Dr. J. B. Mattison, of Brooklyn, praises cannabis highly as an anodyne and hypnotic. It is not a poison; there is no fatal case on record. It must be given in full doses. Small doses are stimulating and exciting; large ones sedative. It is equally useful in dysmenorrhœa, especially of the spasmodic variety, and in painful chronic metritis. In many cases of uterine cancer it allays or prevents pain. It acts well in megrim, in the neuralgias, and headaches so common in anæmic women. It is a safe and excellent hypnotic in insomnia. The tincture must be given in doses of twenty to sixty minims, and of the solid extract, one half to two grains. Farlow recommends the following suppository in dysmenorrhœa, to be introduced every night, beginning five days before the time of the period.

℞. Ext. cannabis indica,
Ext. belladon ..... āā gr. j.
Ol. theobrom ..... ʒ jss.

THE SPECIFIC ACTION OF DRUGS.[1]

By JOSEPH T. SMITH, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE WOMAN'S MEDICAL COLLEGE OF BALTIMORE.

The word specific, as applied to remedies, may have one of two meanings: it means either that the remedy is of infallible efficacy in the cure of a particular species or form of disease, as mercury in syphilis, or it has a special action on some particular organ, as digitalis on the heart.

It is in view of the progress made in our knowledge of the special action of remedies on particular organs or fluids of the body that we felt justified in bringing the subject to your attention, in the form of a report, from this Section, upon the specific action of drugs.

One has but to look over the prescription files in our drug stores to see the desire on the part of the profession for drugs that will do special work. This desire, enhanced by increased knowledge, has done away with the prescriptions of former days, and a few drugs combined for a definite object is the rule rather than the exception.

The desire for specific remedies has always held the foremost place in the medical mind, and it is stronger today than ever before. Dr. John Brown—the Brunonian theory—"assumed that man and other animals possess a peculiar property, termed excitability, by which they are distinguished from inanimate bodies. The agents which support life he termed exciting powers, and these, acting upon the excitability, maintain life. . . . When they, the exciting powers, are in due proportion, health is produced. Diseases arise from either excessive or deficient excitement. . . . According to this doctrine, all medicines are stimuli, and differ from each other in the degree in which they exert their stimulant power—moreover, they are supposed to cause exhaustion by producing previous over-excitement." The whole subject is here made very simple, its extreme simplicity throwing it open to attack. Thus the contra-stimulant, or new Italian, doctrine came upon the stage. This admitted of two classes of medicines, the one called stimulants or hypersthenics, the other contra stimulants or hyposthenics. . . . Contra-stimulants obviate or counteract the effects of stimulants. The desire of such theorists was to regard the body too much as an entity, and not as made up of many and diverse parts inextricably interlocked. The endeavor to look upon the body as a mass of living matter, to be influenced as a whole, was justifiable when a full knowledge of the body was not possible. Our increasing knowledge of the body and of the action of remedies has caused us to gradually abandon the field, until, now, we no longer look for a drug or any combination of drugs that will act as a specific, in the sense that it shall cure a diseased condition, but more and more we look for remedies that will influence for good, not the body as a whole, but specific organs, fluids, or tissues, and thus influence the diseased bodily condition indirectly. Few remedies seem to act directly in curing diseased conditions, as the cinchonas were formerly supposed to do in the various forms of malarial fevers. Headland, in defending himself for putting quinine among restorative hæmatics, quotes at great length Dr. Bence Jones and others, in order to show that a substance like quinine exists in the blood. It was a great advance to lift quinine from its former position, as a specific for the cure of a definite disease, to an agent which simply replaced in the blood a something lost by disease; at the present day we seem to have advanced still further, and quinine is given a definite place as a specific, in that it influences, in a way not thoroughly understood, the growth and development of the germ of Laveran. Recent investigations have thus tended to fully confirm the position of quinine as a specific, only instead of placing it with the

[1] Read before the Medical and Chirurgical Faculty of Maryland, Section of Materia Medica, etc., April, 1892.

restorative hæmatics it more properly takes its place with the germicides. Note, then, the progress that has been made: we are better qualified to diagnose malaria than ever before, and we have in quinine an agent which tends to destroy its cause.

In diphtheria and kindred conditions which might be noted, the chain seems complete, except the last link; we seem to know the cause of the disease, and that the killing of the micro-organisms, or a neutralization of their life-products, would result in a cure; the conditions all seem fulfilled, except the agent which is to act as the destroyer of the cause. The indications are strong at this time that such an agent will be found.

It is difficult at the present day to think of the specific action of drugs without assigning them a place, either as the destroyers of micro-organisms or the neutralizers of the products of their life; no one need, however, be told how great has been our disappointment in this direction. The future, if one may judge from the signs of the times, has much in store, and the new hygienic laboratories promise, in the investigation of the products of bacterial life and the antidotes to the poisons thus formed, much that is of value in ennabling us to treat diseases by destroying their cause. The chemistry of the body is about to assume an importance unknown before, and doubtless in this direction we are to see new fields opened up for the display of the specific action of remedies. The accessibility of the intestinal contents has caused them to be carefully investigated by the bacteriologist, and he seems here again to have opened up a new field for the specific action of drugs. If we can differentiate between the various micro-organisms which produce intestinal disorders, and are able to say whether any diseased condition of the gastro-intestinal tract is caused by bacteria or not, we will be able to apply our remedies with a precision heretofore unknown. This field for the specific action of drugs cannot be better brought to your attention than by noting the remarks of Cantani: "Except in very rare cases," he says, "the destruction of the pathogenic micrococci in the living body will never be realized. All that is required at present is to produce an unfavorable soil for the growth of the micrococci, so that their rapid reproduction may be checked or diminished. . . . Antiseptics may only be given by the mouth when they are not changed or absorbed by the stomach or upper part of the small intestine, so that they reach the ileum unchanged, which is always the seat of the disorder. For this purpose doses of calomel have been used, but set aside as unpractical except in infections of milder form. Bouchard has recommended large doses of finely powdered carbon, napthalin, finely powdered iodoform, and salicylate of bismuth. These substances, given in sufficient amount, can effect an antiseptic action on the fæces, but not, since they are insoluble, on the walls of the intestines. . . . Disinfecting fluids like carbolic acid and corrosive sublimate, given per os, can never produce complete disinfection of the intestines, . . . the only way left is per anum. . . . This is the best way to apply antiseptic fluids which are intended to come in direct contact with disease germs. . . . For antisepsis of the intestines all substances soluble in oil and water may be used. The same applies to astringent preparations, such as alum, salicylic preparations, thymol, aseptol, zincum sulphophenicum, boracic acid, hydrochloric acid, sulphite, and hyposulphite." Cantani speaks well of gallic and carbolic acids. Of gallic acid as being successful in intestinal catarrh with diarrhœa, in dysentery, and typhoid fever. He speaks of a two per cent. solution of carbolic acid with quin. hydrochlor. as a preventive of the development of typhoid fever.

To supply what is lacking in our treatment of diseases of the intestinal tract we must look to a fuller knowledge of the chemistry of the intestinal contents.

As surgery took giant strides after Lister announced his great truth, so we have every reason to believe that the results of bacteriological research, supplemented or completed by the work in hygienic laboratories, will give us a greater point of vantage than we have ever enjoyed before. We will use the drugs we do use with more precision, and lay aside our drugs with more confidence in conditions where they are not indicated. The progress made in assigning to diseases specific causes makes us content with our symptomatic methods of treatment while waiting for new drugs, or the new application of old ones, which shall have the power of exerting specific influences upon the causes already known.

Dr. Abbott, in speaking of immunity, says "that in the serum of the normal circulating blood of many animals there exists a body that is capable, outside the body, of rendering inert bacteria, that, if introduced into the body of the animal, would prove infective. That in many instances infection may be looked upon as a contest between the bacteria and the tissues, carried on on the part of the former by the aid of the poisonous products of their growth, and resisted by the latter through the agency of proteid bodies normally present in their integral cells. That when infection occurs it may be explained either by the excess of vigor of the bacterial products over the antidotal or protective proteids eliminated by the tissues, or to some cause that has interfered with the normal activity and production of these bodies by the tissues. That phagocytosis, though frequently seen, is not essential to the existence of immunity, but is more probably a secondary process, the bacteria being taken up by the leucocytes only after having been rendered inert through the normal germicidal activity of the serum of the blood and other fluids of the body."

In this almost unexplored domain of immunity there opens up many possibilities for the display of the specific powers of drugs.

As an example, we are in a position to believe that, in so far as the specific influence of cod-liver oil and creosote in the treatment of phthisis are concerned, they may act by increasing the antidotal or protective proteids eliminated by the tissues. Brunton says, in speaking of cod liver oil in inflammations, as bronchitis, newly developed cells are present in great abundance, but nutrition is so defective that they cannot take on the character and functions of mucous cells, and hence, in order to allow them to form a new mucous membrane, they must be supplied with a readily assimilable nutritive material. This is probably the explanation of the benefit obtained by the use of cod liver oil in bronchitis and other diseases dependent on malnutrition.

There are many conditions which we are called upon to treat that can have no relation to either bacteriological or chemical causes, such as the valvular heart diseases, the many forms of destructive kidney affections, etc. These seem to present the most unfavorable field for the action of specific drugs; the drugs to be effective must be specific in the sense that they influence special organs.

From our present knowledge in regard to this large class of cases, we may quote from Dr. Goodhart, in an article on the treatment of Bright's disease:

"It is always a thankless task . . . to question the value of any particular treatment by drugs. . . . But it is well to ask ourselves occasionally what we are really sure of, for, unless we do, there is a certainty of our being ultimately effaced by routine, and there are few things worse than that for the patient. And I incline to think that routine has laid too much hold upon us in renal disease. . . . There is no drug of which we can say that it will 'go for' the inflammation; there is no drug, that I know of, that can be depended upon to lessen the output of albumin. Thus it is that we have to depend upon indirect measures, . . . and it is just in the reactions to these measures that the individualism of the patient appears, and I should be glad to hear it stated on authority, what it is difficult to find in books, that even such simple measures as these, valuable as they are in their place, are measures often of severity, to be applied with judgment. . . . Who cannot recall the

memory of cases where pulv. jalap co. has done unmitigated harm? where vapor baths, instead of relieving, have increased the distress? where fluid diet as a means to diuresis has repeatedly upset what little power of digestion remained to the patient? where individualism revolted at the upset of habit?"

What we believe to be true of the kidneys is true of other organs; their diseased conditions are least likely to be influenced by specific remedies. In such conditions the individualism of the patient most forcibly asserts itself; we learn most emphatically the uselessness of drugs in effecting a cure; we are taught to select from the materia medica a few drugs, not as specifics, but as aids, often of secondary importance. Food, clothing, regular habits of life, care and attention to individual habits, and the observance of hygienic laws, are of primary importance; our drugs being used simply to meet special indications as they arise, and in this sense only do they deserve the name of specific. No one can speak of the specific action of drugs without a reference to mercury in syphilis. Our advance here has not been as great as we had a right to expect. A disease presenting such well-marked symptoms as syphilis, and a drug, such as mercury, having such control over it as to lead Dr. Bulkley to say "that mercury alone possesses the true anti-syphilitic power," would seem to possess advantages for the study of the specific action of drugs equal to that of quinia in malarial fevers. The report from the Buda-Pesth laboratory, that a certain bacillus has been found in syphilitic growths of various kinds, may help to solve for us the cause of the disease; but at present Dr. Bulkley about covers the ground when he says: "During the early stages of syphilis, iodine, with its compounds, seems to exert very little effect, whereas the results following an active and efficient mercurial course are often most striking and satisfactory. . . . My more common method of treatment of the later manifestations of syphilis is by means of the old mixed treatment, where a minute dose of mercury is combined with a moderate dose of an iodide, with iron, and a bitter tonic; if the symptoms do not yield, the active elements of the treatment are increased until the desired effect is produced."

We have thus endeavored, in the brief time allotted us, to indicate the general line of advance in our study of the specific action of drugs. We have purposely refrained from considering individual drugs, as that would have opened up too vast, and, in many respects, uncertain, a field; moreover, the practical application of the individual drugs are more or less familiar.

1010 Madison Avenue.

Extirpation of the Larynx.—The number of cases in which the operation of removal of the entire larynx has been successfully performed is gradually increasing. The latest of these was recorded by Professor Wolff at the recent session of the Surgical Congress at Berlin, where the patient was exhibited eight months after the operation. The interest of the case is enhanced by the fact that, by means of an artificial larynx, invented by Professor Bruns, the patient is able to speak and sing, as illustrated before the Congress by his recitation of a monologue from Schiller's "William Tell" and his singing of "Gaudeamus igitur."—*Lancet.*

Sanitation of Cemeteries.—M. Brouardel, the Dean of the Paris Medical Faculty, M. Ogier, and M. Du Mesnil have reported to the Academy of Medicine concerning the sanitation of cemeteries. Their investigation has demonstrated that the speedy or slow destruction of the corpse is in direct proportion to the quantity of air which reaches it; in chalky soil, through which air permeates with difficulty, dead bodies become transformed into a fatty substance, *gras de cadavre*, which lasts five or ten years; but if air freely circulates about dead bodies they are completely destroyed at the end of a year, owing to the action of certain insects.

Clinical Department.

ECTOPIA TESTIS, WITH AN ILLUSTRATIVE CASE.

By EDWARD A. BALLOCH, M.D.,

INSTRUCTOR IN MINOR SURGERY, MEDICAL DEPARTMENT, HOWARD UNIVERSITY, WASHINGTON, D. C.

E. C. S——, aged forty-seven, clerk, married, but always childless. The testicles have never descended into the scrotum. He has always had some sexual desire, but never very strong. He never suffered any inconvenience by reason of the malposition of the testicles until winter of 1888, when he began to have attacks of pain and swelling in the left one. These attacks increased in frequency and severity, until walking, or, in fact, any movement, became well nigh impossible and life was a burden to him. After a faithful and unsuccessful trial of all other means, this testicle was removed from the groin by a surgeon of this city, in May, 1889.

The operation was successful, and relief was immediate and lasting until December, 1890. At this time the patient began to have attacks of orchitis in the remaining testicle, which, in spite of treatment, gradually became so severe that his general health began to suffer, and he begged that this testicle might be removed to end his sufferings.

Examination revealed the following conditions: Spare but fairly well nourished. Family history good. Mitral systolic heart murmur, but vital organs otherwise normal. Scrotum rudimentary. Penis under-sized but fairly well developed. Well-healed scar in the left groin from former operation. In the right groin an oval subcutaneous tumor, about three inches long by one in width, extending in a direction upward and outward from the inguinal ring. The tumor was very tender and intolerant of manipulation, but firm and solid to the feel. It was quite freely movable in the direction of its long axis, and somewhat so transversely, but could not be lifted from its bed. There was no particular impulse on coughing, and no signs of the presence of the intestine either behind or in front of the tumor could be detected. He has had but an extremely feeble sexual desire since the removal of the left testicle, and practically none since the one in the right groin became involved. It was the patient's earnest wish to have the organ removed, and, considering the inflamed condition, its functional inactivity, and the un success following a faithful trial of all other means, his request was acceded to. By way of parenthesis, it may be added that an element of no small weight in reaching this conclusion was the fact that the patient's wife had undergone an operation for removal of both ovaries and Fallopian tubes early in 1889.

From a Malthusian stand-point Mr. S—— and his wife may now be said to constitute an ideally perfect couple.

The operation was performed on March 5, 1891, by Professor N. F. Graham, assisted by Dr. T. A. R. Keech and the writer. The parts were carefully disinfected and every precaution in the way of sterilizing hands, instruments, ligatures, and dressings was taken. Upon incision the testicle was found to lie half within and half without the external inguinal ring, and to be enlarged, inflamed, and very vascular. It was firmly grasped at its centre by the pillars of the ring. The constricting bands having been divided by a few touches of the knife, the testicle was released. The cord, which lay at the back of the tumor, was very short, and entered the organ at its centre. The testicle was carefully freed from all adhesions, until only the cord remained. A stout control-ligature was passed through this and the ends tied. The cord was then firmly compressed between the blades of a thumb-forceps and cut. No hemorrhage followed, but as a measure of precaution the stump was transfixed by a double silk ligature and each half separately tied off *en masse*. A drainage-tube was inserted, the edges of the

wound being carefully approximated by deep and superficial sutures, and a dry dressing of iodoform and gauze and sterilized absorbent cotton applied. The convalescence was rapid and uneventful.

Retained testicle, while not an uncommon condition in infants and children, is not frequent in adults, the usual course of things being for the organs to descend at puberty, if they have not done so before. When found in adults monorchism is the rule, and complete cryptorchism the exception. Either one or both testicles may escape from the inguinal canal and lodge in the abdominal wall, the femoral canal, or the perineum. This form of malposition is known as ectopia testis, and is quite rare.

The causes of non-descent or retention may be broadly classified into two, viz., 1, arrest of development; 2, mechanical obstacles. Among the latter may be enumerated small inguinal rings, a short spermatic cord, a transverse position of the testicle, non-communication between abdomen and scrotum, and blocking of the internal inguinal rings by a coil of intestine, or even by one of the kidneys, as in a case reported by Birsch-Hirschfeld. Chelius and others of the earlier writers state that when the testicle is retained in the groin the cord will be found to be very long. In the case now reported, as in that of Hubbard, noticed further on, the cord was, on the contrary, found to be very short.

The retained organs, particularly in ectopia testis, are much exposed to blows and other injuries, and are very prone to undergo malignant degeneration. Most of the operations reported have been for malignant disease. When the testicle descends before puberty its descent is apt to be followed by a knuckle of intestine causing a hernia.

In Hubbard's[1] case the retained testicle was complicated by a large multilocular hydrocele, the cord being short. Attacks of orchitis in misplaced testicle are not infrequent, as in the present case, and when they do occur, are apt to occasion great pain and suffering, particularly if the testicle be trapped by fascia or clasped by the walls of the inguinal canal.

The question of operative relief for this condition resolves itself into a choice of one of three methods of procedure, viz.: 1, To push the testicle back into the abdomen and retain it by a truss; 2, to bring it down into the scrotum and fix it there, or, in case the scrotum be rudimentary, to form a new scrotum from the integument of the thigh; 3, to remove the affected organ. Against the first method there was urged by the older writers, particularly by John Hunter, the objection that a testicle in the abdominal cavity was incapable of functional activity. Numerous instances, however, of cryptorchids with full virile powers have completely disproved this somewhat fanciful assertion, and the generally accepted opinion now is that simple non-descent or retention, uncomplicated by degeneration or atrophy of the organs, is no bar to full virility.

In cases where a loop of intestine is found to be adherent to a retained testicle, the proper course is to push both back into the abdomen and apply a truss. If no adhesions exist between the testicle and the gut, a truss may be applied, with a small pad above the testicle and below the gut, in the hope of forcing the former down and keeping the latter back.

In cases where the testicle is in the groin and is not diseased or functionally inactive, an attempt may be made to bring it down into the scrotum and fix it there, particularly if the scrotum be roomy enough. Williams,[2] of Brooklyn, reports a very successful case of this character. If the scrotum be rudimentary a new one may be made, by a plastic operation, from the skin of the thigh. Unless imperatively demanded, it would seem that the risks run by this operation were not justified by the ends sought to be attained. A testicle in the groin, if not diseased, is as good functionally as one in the scrotum, and if diseased its entire removal is indicated. In Williams's case the operation was done largely as a moral measure, to give the patient the assurance that he was a full and perfect man.

The question of inguinal castration is one which in the past has excited a great deal of controversy, more so than it is ever likely to do again. The weight of opinion among the older authorities was to the effect that the operation was much more fatal than scrotal castration, and that it was to be avoided except when absolutely demanded.

Monod and Terillon,[1] in 1880, gave this question careful study, and analyzed the cases recorded up to that date. They show conclusively that the mortality does not depend upon the operation itself, but upon the causes necessitating operation (an analysis of forty-two inguinal castrations for tumors of various sorts showing a mortality of sixteen per cent.), but that most of the deaths were the result of an extension of malignant disease. They believe the operation perfectly justifiable in cases of pain and swelling, and give fifty cases with only one death from peritonitis.

The cases upon which these opinions were based were taken from the older literature of surgery; and if upon such a record as this the operation was pronounced justifiable, there should be no question as to its propriety at this date.

Cryptorchism is not uncommon in the lower animals, and medical literature, particularly the French, contains many articles upon this condition and the methods of operation, which do not differ essentially from those practised upon the human animal.

The castration of women is popular at present, and the castration of men is sometimes necessary, but I have not been able to find a case in which both man and wife have lost the organs essential to conception.

REPORT OF TWO CASES OF "HEMIALBUMINURIA."

By E. L. JONES, M.D.,

FLORENCE, ALA.

On November 19, 1889, I examined, for life insurance, Mr. J. C. J——, aged about thirty-five, mechanic; a man of perfect physical development, good family record, and previous perfect health. Upon testing his urine I was astonished to see a dense white precipitate from nitric acid; proceeding to apply the heat-test, a few drops of acetic acid were added, which also gave a dense white precipitate, and upon heating, each precipitate entirely cleared up. In other respects the urine was normal. Not knowing what I had found, I proceeded to look the subject up, and ascertained that it was first discovered by Dr. Bence Jones in a case of osteo-malacia, and by him named hemialbumin; others have given it different names.

The second case was that of a mulatto, aged thirty-seven, who presented himself on November 26, 1891, on account of a general malaise and lassitude, with headache; urine, scanty. Three years before, I had treated him under exactly the same circumstances, except as to the presence of hemialbumin. In this case the chemical reactions were the same as in the first case, urine otherwise normal, with no sediment for microscopic examination. He was soon relieved by regulation of diet and mild diuretics. Daily examinations of the urine were made for a week, but no hemialbumin was found except in the first instance.

In searching the literature at my command, I find in several independent authorities allusion to this condition having been observed by Bence Jones and Kuhne, and as no other observations are recorded, I judge its occurrence must be very rare. I do not remember having seen any allusion thereto in a general reading of current medical

literature for five years. Whether its occurrence is of any significance or not, is as yet undecided, but judging from my having seen it twice in at most only a few hundred examinations of urine, it must be more common than supposed, in many instances being pronounced albumin from careless testing, which may also explain how it is sometimes so easy to cure "Bright's disease." I know that it is the practice of many good physicians to apply only the nitric-acid test for albumin, and where they get the dense white precipitate they consider it entirely unnecessary to proceed further, when possibly the heat test would reveal quite another state of affairs It was to call attention to this practical point that prompted me to report the above observations.

Progress of Medical Science.

Treatment of Vesicular Keratitis.— Drs. Wecker and Landolt think that it is not sufficient in vesicular keratitis, or herpes of the cornea, to evacuate the contents of the vesicles by puncture, inasmuch as the liquid is soon reproduced. The parietes of the vesicles should be removed with forceps, or the lesion should be well scraped with a cataract-knife, and the eye covered with a compress. If the patient will not submit to this operation, they recommend introducing into the eye a pinch of calomel or other powder capable of destroying the thin walls of the vesicles by friction. In addition, instillations of eserine or of pilocarpine are useful.—*Therapeutic Gazette.*

Syphilis of the Kidney Surgically Considered.— Dr. Israel (*Le Mercredi Médical*, February 24, 1892) made a communication to the Open Reunion of the Berlin Surgeons, in which he says that syphilitic affections of the kidney have not till now found a place in works on renal surgery, because, on the one hand it would seem exceptional that they could call for operative interference, and on the other, their confusion with true surgical diseases of the kidney seems impossible. Up to the present time we know two forms of renal syphilis—interstitial nephritis and gummata. The latter in the published cases reached such a volume that there was no occasion for a differential diagnosis between them and renal tumors. In the first case which the author relates, to show that philitic kidney may at times have a surgical interest, a woman, aged twenty-three, who had probably contracted syphilis four years previously, had been well until three weeks before seen, when frequent micturition, increased thirst, abdominal cramps, and continual rachialgia were noted, and a tumor began to show itself in the right hypochondrium. The right kidney was found decidedly increased in size on palpation, was of hard consistence, uneven surface, and painless on pressure. The augmentation of volume, the hardness of the organ, and the loss of flesh on the part of the patient, all favored a diagnosis of malignant neoplasm. Nevertheless the presence in the urine of epithelium of the pelvis, and globules of pus, caused hesitancy, although these elements are found in malignant tumors. This diagnosis was further opposed by the frequency of micturition, thirst, and increased volume of urine with feeble density, traces of albumin, and the presence of hyaline casts, symptoms rather favoring a diagnosis of renal sclerosis. Syphilis was thought of, and iodide of potassium ordered, under which the tumor diminished in an appreciable manner, while the patient gained ten pounds and a half in about two months. About this time epithelial masses, in form of a precipitate of fine white particles, began to be constantly present in the urine, and as their diagnostic importance or cause could not be determined, as neither the author nor others who saw them had ever seen a similar condition, after three months of observation an exploratory incision was determined upon to clear up the nature of the process. The capsule was found much thickened, œdematous, and solidly adherent to the kidney. The upper half of the kidney was of normal volume, and regular surface and consistence. On the contrary, the inferior part was hypertrophied, enlarged, hard, and covered with decided elevations. Nephrectomy was therefore decided upon. Examination of the organ showed the condition to be one of interstitial nephritis, with hyperplastic peri- and para-nephritis, the lesions so joined together as to give the impression of a tumor. None of the alterations explained the peculiar elements found in the urine, which continued to be present afterward, although the opposite kidney was not increased in size. The author thinks there was no doubt of the case being one of syphilitic nephritis, as the lesions were characteristic, but in his experience the unilateral nature of the affection is without parallel.

In a second surgical case we are told of a condition of atrophy of the kidney consecutive to syphilitic gummata. In May, 1889, a young man began to suffer from spontaneous pains in the region of the lower part of the left thoracic wall. Five months later the character of the pains changed, and now sensations of intense burning came on in attacks lasting two or three minutes from ten to seventeen times daily. An abscess, thought to be splenic, was opened at the tenth rib, and a white, puriform, lumpy substance evacuated. The pains decreased but did not disappear. In October, 1890, the patient came to the author. The urine contained pus and albumin, but no tubercle bacilli. A distinct, resisting, diffuse fulness was to be felt in the region of the kidneys. A paranephritis, with probable renal destruction, was thought probable, and nephrectomy was decided upon. Anatomically this was found to be the case, but etiologically the renal disease was due to syphilis. The atrophied kidney was completely filled with gummous products shut in by a fatty capsule, thickened and transformed into a veritable sac. The patient made a good recovery. Such an advanced stage of degeneration is rare in syphilis, and till now has not received surgical treatment. These observations have a clinical, anatomical, and therapeutic interest, and teach that syphilis should be included in the surgical affections of the kidney.

Nitroglycerine Subcutaneously in Poisoning by Illuminating Gas.— Dr. Hoffmann (*Allgemeine Med. Centr. Ztg.*, 1891) reports a case of poisoning by illuminating gas where the patient breathed the air of a small room into which gas had escaped from an open burner from 11 P.M. till 9 A.M. Four grammes of ether were injected under the skin without result. One milligramme ($\frac{1}{60}$ gr.) of nitroglycerine was injected into the præcordial region. One-half a minute later the pulse became stronger and the respiration deeper. From then on the pulse was regular and strong. One hour later the patient could swallow several spoonfuls of coffee. That afternoon there was headache, dyspnœa, and malaise, but by the next day entire recovery had taken place.

Treatment of Diabetic Coma.—Dr. Reynolds (*Medical Chronicle*, 1891, p. 338) having met with about twenty fatal cases of diabetic coma, all fatal except two, recommends the plan of treatment employed in these last. After giving an aperient he made his patient with impending coma (drowsiness, pain in epigastrium, labored breathing) drink about a gallon of water during the night, and take every hour sixty grains of citrate of potash. The dose of the latter drug was diminished, but the treatment appears to have been kept up for three days, by which time all the alarming symptoms had disappeared. In the next case there was an acetone odor, with slight breathlessness and drowsiness; he ordered castor-oil, large quantities of fluid, and thirty to sixty grains of citrate of potash every hour. During the next thirty-six hours he took one and a half gallon of fluid, with the result that the symptoms disappeared.

MEDICAL RECORD:

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, August 6, 1892.

THE ETIOLOGY AND PREVENTION OF YELLOW FEVER.

AT a time when epidemics of destructive diseases are specially feared, when there are reports from various parts of the world of the extension of cholera, the spread of typhus, and the invasion of new districts by the yellow fever scourge, the profession in this country, and in fact everywhere, is interested in any new facts which may throw light into dark places, or explain the present scientific status of things, known or unknown. Within the past few years the bacteriologists have given very satisfactory evidence as to the important part which pathogenic micro-organisms bear to the etiology of a large number of diseases; and while inferentially much more may be expected in the same line of inquiry, we are occasionally brought to a standstill by a mere report of progress with a simple encouragement to continue the work. A forcible reminder of the latter condition is given in the admirably exhaustive report of Major George M. Sternberg, U. S. A., on the etiology and prevention of yellow fever, just published by the United States Marine Hospital Service, by direction of the Secretary of the Treasury. The investigations which have resulted in the report in question were undertaken by command of the Government, and were made principally in Cuba and in such portions of the United States as have been infected with yellow fever since 1888.

In view of the well-earned reputation of Dr. Sternberg for scientific accuracy in bacteriological studies, it is unnecessary to say that there is scarcely anywhere to be found a gentleman who could be better fitted, by experience and training, for the work assigned him. It therefore becomes doubly interesting to note his conclusions, and utilize such data as are offered to the practical test of prospective experience.

Notwithstanding the laudable ambition to discover a specific infectious germ for yellow fever, it certainly requires on his part no small amount of courage to declare that the results of his work in that direction have been negative. With a true scientific spirit of accuracy, he declares tersely, and very much to the point, that the specific infectious agent in yellow fever has not been demonstrated; and this, too, after the most careful, conscientious, and thoroughly impartial critical study of the claims of other investigators, not to mention his own frustrated hopes in the same direction. Numerous micro-organisms were found in the blood of yellow-fever cadavers, but none that was positively distinctive. Blood, urine, and crushed liver were not pathogenic when obtained from recent autopsies and injected hypodermatically in moderate amount into rabbits and guinea-pigs. The opposite was the case, however, with liver tissue preserved in an antiseptic wrapping at a temperature of 20° to 30° C., for forty-eight hours. This pathogenic power appeared to be due to the micro-organisms undergoing some change during that time, or to the toxic products developed as a result of their growth.

While it seems reasonable to suppose that a specific germ may exist, there are so many modifying circumstances to be taken into account, so many complex processes to be controlled, that at present the usual methods of research are inadequate to isolate it. That this difficulty is fully appreciated by our distinguished countryman is shown by his highly instructive comment, that "many facts relating to the origin and extension of yellow fever epidemics give support to the inference that the specific infectious agent is present in the dejecta of those suffering from the disease, and that accumulations of fecal matter and of other organic material of animal origin, furnish a suitable nidus for the development of the 'germ' when climatic conditions are favorable for its growth. It may be that such a nidus is essential, and that the culture media usually employed by bacteriologists do not afford a suitable soil for this particular microbe. It is also possible that its development depends upon the presence of other micro-organisms found in fecal matter, which give rise to chemical products required for the development of this one."

The practical bearing of this observation is evidenced by the special manner in which yellow fever propagates itself, in that it will only grow in a special nidus, that it is always imported, that its area of infection in seaports is quite limited, that it extends slowly, is always carried by infected persons or clothing, and affects only such unacclimated persons as come within the area of infection

Granting what appears to be perfectly reasonable, that the dejecta of yellow-fever patients are infectious, it is natural to agree with Dr. Sternberg in recommending that such material should never be thrown into privy-vaults or buried without previous thorough disinfection, and all soiled clothing, bedding, and the like should be similarly treated by the most approved methods of fumigation. This rule, thoroughly enforced, together with an efficient quarantine and proper attention to the sanitary police of our exposed seaport cities, will, Dr. Sternberg believes, effectually prevent this pestilential disease from obtaining a foothold within the limits of the United States.

Although the points thus far noticed appear of most importance, considering the main purpose of the work, there are others, bearing upon the natural history of the disease, which are incidentally instructive as corroborating statistically what is already pretty well known. These may be alluded to incidentally, in order that a suitable practical turn may be given to the painstaking and elaborate investigations of the talented author.

At the risk of repeating part of what has already been said, but as a necessary introduction to our concluding comments, we quote his admirable definition of yellow fever, as reproduced from his article in Wood's "Refer-

ence Handbook of the Medical Sciences:" "A specific infectious disease, contracted by exposure in infected localities; characterized by a single febrile paroxysm of short duration (two to five days), by the presence of albumin in the urine, an icteric color of the skin, and a tendency to passive hemorrhages from mucous surfaces—especially from the stomach—producing 'black vomit.'"

No new facts have been introduced bearing upon the well-recognized methods of invasion, the influence of climate, the significance of pathological lesions upon mortality, nor the average immunity from second attacks in acclimated individuals. It is safe to say, in passing, that the theory of personal contagion is quite effectually overthrown, and the weight of evidence is entirely on the side of such as believe in the direct influence of infected localities. As regards treatment of the disease, the practitioner will be glad to learn that it is still considered a self-limited disease, and that little else is to be done save on the expectant plan. Considering the limitation of the disease to certain infected localities and the well-known means of preventing its extension, there is little to be apprehended from any wide spread epidemic in this country. The history of previous epidemics has proved this in their short-lived duration. The very fact that the infectious area is limited, affords the best possible chances of escape for unacclimated persons, provided the infectious materials are not carried with them. But quarantine of itself amounts to nothing, unless combined with the most complete sanitary regulations; nor does frost always kill the infectious principle.

These are some of the many points in the natural history of the disease that may tend to increase our confidence in prophylactic measures, and give us hope of limiting its spread when it has already gained a foothold. To be forewarned is to be forearmed. We can thus calmly await events and hope for success accordingly.

THE HIGHER EDUCATION OF WOMEN IN GERMANY.

The question of the co-education of the sexes has reached the stage of inquiry in Germany. A short time ago the Government addressed a note to all of the universities, calling for an expression of opinion from each as to the expediency of admitting women to attendance upon the lecture courses. Several of the universities, among the most important of which may be mentioned that of Gottingen, have declared themselves as unqualifiedly in favor of admitting both men and women on an equal footing, while others think that the time is not yet ripe for such a radical change, and some have expressed themselves as adverse to the innovation.

Professer Hermann Grimm, of the University of Berlin, has recently published a communication on the subject in the *National Zeitung*, in which he takes the ground of a moderate conservative. He seems to be unwilling to admit women to his own lectures from purely personal motives, because he is accustomed to speak to young men only, and cannot bring himself to address a mixed audience, but he has apparently no objection to the principle of co education. He confesses that he has been converted from the theory that women are intellectually inferior to men, or that the so-called higher education will unsex them and render them incapable of the normal functions of wifehood and motherhood. He admits that many women have to devote a large portion of their time and energy to business details, while still remaining devoted wives and mothers, and he confesses that there is no *a priori* reason why the same time and energy should not be devoted to intellectual pursuits without detracting from the purely feminine duties. He apparently, however, ignores the fact that there are more women than men in the civilized world, and that some must, therefore, of necessity forego the normal relationship of wife and mother, and that it is the right of each individual woman to elect whether she shall devote her life to science exclusively, or shall take upon herself the arduous task of bearing and forming a new generation. Liberty is the watchword of our day and generation, and while we think that the highest office of woman is that of child-bearing and child-training, we cannot deny to her the following of business or scientific pursuits if she so will.

Germany is one of the last countries in Europe to hold out against this view, but the ground has evidently been broken over there. "Men have no right," Professor Grimm says, "to forbid women to avail themselves of the advantages offered by public institutions of learning, in order to obtain the knowledge of which they feel the need, for there exists to-day a general disinclination to be unjust." This declaration, coming from a conservative in conservative Germany, is of the highest significance, and foreshadows the final breaking down of all barriers in that country to the higher education of women. They may not be admitted to the same classes with men, and there is no reason why they should, either in Germany or elsewhere. Let them be only given equal opportunities with men to acquire knowledge, and that is all they can with justice demand. And that is what they are evidently on the eve of acquiring in Germany at the present day.

THE CHOLERA.

The latest cable reports at the time of writing are to the effect that the cholera continues to advance in Western Russia, the occurrence of a number of cases in Warsaw and other parts of Poland being now admitted by the authorities. In several cities all mail matter from the infected districts is disinfected before it is allowed to be distributed. In Tashkend, one of the chief cities of Turkestan, very serious riots have occurred in consequence of the stringent sanitary measures taken by the authorities to prevent the spread of the disease. The mob destroyed the residence of the Russian Governor and killed several of the officials. The military were called out, and after trying vainly to disperse the rioters with bayonets, fired into them, killing about one hundred and wounding many more.

That the plague is more serious than has been admitted by the authorities, is indicated by the report of a newspaper correspondent, who states that during July over fifty thousand persons died of cholera in Russian Caucasus alone. The Government has established an orphanage in Astrakhan for children whose parents have been carried off by the disease.

The question whether there is cholera in Paris or not seems still undecided, with the probabilities now in favor

of its being true cholera, preceded by some municipal lying in order to prevent a "scare." Now that the disease is under control the authorities appear willing to admit its real nature. Such kind of deception, if deception it was, is as short-sighted and foolish as it is scandalous.

News of the Week.

The Late Dr. Charles D. Scudder.—The following resolutions were passed at a meeting of the Medical Board of the French Hospital:

Whereas, It has pleased Almighty God to suddenly remove from among us Dr. Charles D. Scudder, for a number of years a most valued member of the Medical Board of the French Hospital in the City of New York, we, his former colleagues in the Hospital, do hereby

Resolve, That by his death the Hospital has suffered a most grievous loss and will severely feel the lack of his wise counsel, his loving and faithful work, and his enthusiastic co-operation in all that tended toward improvement. And be it further

Resolved, That we, his associates in the Hospital, do each and all feel that we are bereft of a personal friend, whose consummate acquirements, whose loftiness of manhood, and whose deep religious faith commanded our admiration and our love. And it is further

Resolved, That in this, their irreparable loss, our heartfelt sympathy is extended to all who were near and dear to him.

American Social Science Association.—The General Meeting of this Association will be held in the Town Hall in Saratoga, beginning Monday, August 29, and closing Friday, September 2, 1892. The opening address will be given by the President, H. L. Wayland, D.D., of Philadelphia, Monday evening, August 29th, at 8 P.M. On the same evening, at 9 P.M., Rev. J. M. Buckley, D.D., will address the Association. The departments will hold sessions as follows:

Tuesday, August 30th. Department of Education.—Remarks by the Chairman, Merrill Edwards Gates, LL.D., President of Amherst College. Report of the Secretary, Dr. Louise Fiske Bryson, of New York, on "Education as a Therapeutic Measure." A paper by Miss C. M. Hewins, of the Hartford Library, Conn., on "Public Libraries as a Factor in Education." A paper on the "Educational Value of Modern Economics," by Starr Hoyt Nichols, Esq., of New York. A paper on "Art Education in American Life," by Myra B. Martin, of New York. An address on "The Training of the Mentally Defective in Childhood," by Dr. Isaac N. Kerlin, of Elwyn, Pa.; followed by a report of the General Secretary on "Training Insane Women to Domestic Industry."

Wednesday, August 31st. Department of Health.—Remarks by the Chairman of the Department, Frederick Peterson, M.D., of New York. A report by the Secretary of the Department, W. D. Granger, M.D., on the "Work of the Health Department since its Organization." A paper by Matthew D. Field, M.D., of New York, on "The Examination and Commitment of the Public Insane in New York City." A paper by Ralph L. Parsons, M.D., of Sing Sing, N. Y., on "Voluntary Commitment of the Insane to Asylums." A paper by Henry Ling Taylor, M.D., of New York, on "American Children Hygienically Considered," followed by debate. An address by W. W. Keen, M.D., of Philadelphia, on "The Modern Surgery of the Brain." A paper by Frederick Peterson, M.D., of New York, on "The Old and the New Phrenology."

Thursday, September 1st. Department of Jurisprudence.—Remarks by the Chairman of the Department, Professor Francis Wayland, of New Haven, Conn. Subject, "Has the State abdicated?" A paper on "The Great Coal Combination," by C. La Rue Munson, Esq., of Williamsport, Pa. A paper on "Municipal Government," by Albert Shaw, Ph.D., of New York. A paper on "County Jails," by Edward B. Merrill, Esq., of New York. A paper on "Crime and Penalty in the United States," by Hon. Andrew Dickson White, of Ithaca, N. Y.

Friday, September 2d. Department of Social Economy.—Address by the Chairman of the Department, F. B. Sanborn, of Concord. Report by the Secretary of the Department, on "The Sweating System," by Joseph Lee, Esq., of Brookline, Mass. A paper on "The Sweating System in Massachusetts," by H. G. Wadlin, Esq., Labor Commissioner of Massachusetts. A paper on "Conditions observed by a Dispensary Physician in New York in regard to the Sweating System," by Annie S. Daniel, M.D., of New York. A paper on "The Actual State of Tenements in Boston where Work is Carried on," by William F. Hicks, Esq., of the Boston Board of Health. Papers on "The Sweating System in Europe," by Rev. John Graham Brooks, of Brockton, Mass., and on "Remedial Measures Proposed in England by the House of Lords Commission, with their Results," by Mr. David F. Schloss. An address on "Architecture in Relation to Life," by Mr. Barr Ferree, of New York.

The headquarters of the Association will be at the United States Hotel, as usual, where members and guests of the Association will be received at the reduced rate of $3 a day. F. B. Sanborn, *General Secretary.*

Venesection in Pneumonia.—Dr. C. C. P. Clark, of Oswego, writes that in his article on the "Lost Art of Venesection," in the Medical Record of July 9th, he made the statement that he could not remember having lost a patient after bleeding. What he intended to say was that he could not remember having lost a patient from pneumonia after bleeding him.

Programme of the Sixth Annual Meeting of the American Orthopedic Association.—The meetings will be held at the New York Academy of Medicine, September 20, 21, and 22, 1892. The Association will be called to order daily at 9 A.M. There will be an afternoon session at 2 P.M. On Tuesday evening, at eight o'clock, Dr. Lewis A. Sayre will receive the members and guests of the Association at his house, No. 285 Fifth Avenue. At eight o'clock on Wednesday evening the Annual Dinner will be held in the banquet-room of the Academy of Medicine.

First Day, Tuesday.—The following papers will be read: "The President's Address," by Dr. Benjamin Lee, of Philadelphia; "Report of a Case of Spontaneous Dislocation of the Hip-joint," by Dr. B. E. McKenzie, of Toronto; "Adduction Following Fracture of the Neck of the Thigh-bone," by Dr. H. Hodgen, of St. Louis; "Osteitis Deformans, with a Report of Two Cases," by Dr. Henry Ling Taylor, of New York; "Lateral Dislocation at the Knee-joint Due to Local Disease, or Paralysis, with Especial Reference to Treatment," by Dr. T. Halsted Myers, of New York; "Plaster-of-Paris Orthopedics," by Dr. A. J. Steele, of St. Louis; "The Orthopedic Treatment of Infantile Spinal Paralysis," by Dr. John Ridlon, of Chicago; "A Report of Two Years' Operative Work in the Hospital of the Ruptured and Crippled," by Dr. V. P. Gibney, of New York; "Lateral Curvature," by Dr. E. H. Bradford, of Boston; "The Classification of Hip Disease," by Dr. R. W. Lovett, of Boston; "A Study of Some of the Problems in the Mechanical Treatment of Hip-joint Disease," by Dr. Newton M. Shaffer, of New York; "Experiments Demonstrating the Etiology of the Various Deformities in Hip-joint Disease," by Dr. A. M. Phelps, of New York; "Some Remarks on the Etiology of Club-foot," by Dr. Samuel Ketch, of New York. Discussion to be opened by Dr. J. K. Young, of Philadelphia. "At What Age Shall the First Treatment of Congenital Club-foot be Instituted?" by Dr. Augustus Wilson, of Philadelphia. Discussion to be opened by Dr. C. C. Foster, of Cambridge.

Second Day, Wednesday.—The following papers will be discussed together: "The Non operative Treatment of Congenital Club-foot," by Dr. A. B. Judson, of New York; "The Non-operative Treatment of Club foot in Young Infants," by Dr. R. W. Lovett, of Boston; "Manual Replacement in the Treatment of Club-foot," by Dr. Ap Morgan Vance, of Louisville; "The Treatment of Club-foot by Continuous Leverage," by Dr. Henry Ling Taylor, of New York; "The Place of Traction in the Treatment of Club-foot," by Dr. Newton M. Shaffer, of New York; "The Use of the Wrench in the Treatment of Club-foot," by Mr. Robert Jones, of Liverpool. Discussion to be opened by Dr. A. M. Phelps, of New York, and Dr. Roswell Park, of Buffalo. The following papers will be discussed together: "The Operative Treatment of Club-foot," by Dr. DeForest Willard, of Philadelphia; "Analysis of Bone Operations in Club-foot, especially Enucleation of the Astragalus," by Dr. V. P. Gibney, of New York; "Treatment of Resistant Club-foot," by Dr. E. H. Bradford, of Boston. Discussion to be opened by Dr. L. A. Sayre and Dr. J. B. Bryant, of New York.

Third Day, Thursday.—The following papers will be read: "An Easy Way to Hold the Operated-on Club-foot in the Corrected Position while the Plaster-of-Paris Splint Sets," by Dr. H. M. Sherman, of San Francisco; "Means for the Prevention of Relapse in the Treatment of Club-foot," by Dr. B. E. McKenzie, of Toronto; "Necessity for Mechanical Treatment after Operations for Club-foot," by Dr. W. R. Townsend, of New York; "A Case of Club foot with Rare Complications," by Dr. A. J. Steele, of St. Louis. Papers (titles not announced) will also be read by Drs. T. Halsted Myers, of New York; R. H. Sayre, of New York; H. L. Burrell, of Boston; and J. C. Schapps, of Brooklyn.

The following are the officers of the Association: *President*, Benjamin Lee, M.D.; *Vice Presidents*, R. H. Sayre, M.D., H. L. Taylor, M.D.; *Corresponding Secretary*, Royal Whitman, M.D.; *Secretary and Treasurer*, John Ridlon, M.D., 34 Washington Street, Chicago.

Treatment of Rhus Poisoning.—Dr. R. L. Patterson, of Bridgeville, Pa., writes that glyco-phenique, applied according to the following formula, gives greater relief than anything else in cases of poisoning by rhus toxicodendron. It will, he says, relieve the severest case within two hours, and cure it in half the time required under any other method.

℞. Glyco-phenique (Déclat),
Olive oil.....āā equal parts

To be kept in contact with the affected parts by means of absorbent cotton.

If the eyes are inflamed and swollen, the following collyrium should be used:

℞. Acidi borici ..... gr. xij.
Aq. camph.,
Aq. destillata .....āā ℥ ij.
Sig.: Drop into the eyes frequently.

Dr. James M. Griffin, of Brooklyn, died on June 14th. He was born at Plattsville, N. Y., in 1842, and was graduated from the Albany Medical College in 1869. At the time of his death he was President of the Central Throat Hospital and Polyclinic Dispensary, and at a special meeting of the medical board of this institution, held June 15, 1892, the following resolutions were adopted:

Resolved, That in the death of Dr. James M. Griffin this Hospital and Dispensary has lost an able and prominent member, the community a highly esteemed and gentlemanly physician;

Resolved, That during his professional career he distinguished himself by a blameless life, an honorable character, genial sympathy, reverence for truth, and respect;

Resolved, That to his bereaved widow and sorrowing son we tender our heartfelt sympathy and consolation, assuring them that we shall ever cherish in our hearts pleasant memories of his life.

Henry A. Riley, A.B., LL.B., a frequent contributor to medico-legal literature, died of heart-disease, in New York, on June 9th.

Visceral Phlebotomy.—Dr. George Harley has again been treating cases of hepatic disease by means of bold punctures. In the first case the liver was punctured to a depth of eight inches in a patient dying from the combined effects of a greatly enlarged, hard, and inflamed liver, ascites, and marked anasarca. Recovery followed, with no return of the disease. In the second case, the liver, enlarged and inflamed, and the seat of strumous abscesses, was likewise treated. Copious hemorrhage took place through the bile-duct into the intestine. The liver became smaller, and convalescence ensued. Pulmonary phlebotomy is the most difficult form of visceral phlebotomy, the constant movement of the lungs making it far from an easy matter to close the wound; but it has been done, so we are informed, with great benefit to the patient. Dr. Harley holds that visceral phlebotomy should be practised on every accessibly situated internal organ in preference to leeching and cupping.

Unchaste Man.—The Professor of Latin in Columbia College says that there is no single word in any language to express the male equivalent of virgin, that is, a chaste man. Still there have been races, such as the ancient Germans, where chastity in males was a highly esteemed virtue; and it is one also which was diligently taught and pretty well practised by the Christian men who founded this Republic.

The Medical Magazine is the title of a new monthly published in London, by Southwood, Smith & Co.

Dr. Da Costa has resigned the chair of Clinical Medicine in Jefferson College.

Salophen.—Dr. W. H. Flint finds that salophen (acetyl-para-amydo-salol) acts very well in acute rheumatism, given in doses of fifteen grains every three hours.

The Work of State Medical Examining Boards in the United States.—According to Dr. P. H. Millard (*Medical News*), the total number of persons examined by these boards in Alabama, North Dakota, North Carolina, Virginia, and Minnesota has been 1,950. The total percentage licensed was 75.2 per cent. Of 183 graduates of colleges requiring three courses of instruction for the degree of M.D., 179 passed examinations; 4 were rejected, making the percentage passed 97.2. Of 435 graduates of colleges that formerly issued degrees after attendance upon two courses of lectures, 343 passed examinations; 92 were rejected. The percentage passed was 78.8.

Dr. T. W. Hime has successfully transformed small-pox into cow-pox, by inoculating a calf with variolous lymph.—*British Medical Journal.*

An Alarm-bottle for Poisons.—A Canadian named Trottier has invented a simple and ingenious device to be attached to all bottles containing poisons. It consists of a mechanism fastened to the bottom of the bottle, and so arranged that every time the bottle is lifted or moved it rings a little bell. With a death's-head for the eye, and a kind of death-rattle for the ear, it seems as if accidents ought to be entirely avoided.

The Summer Work of the Board of Health.—The physicians comprising the "summer corps" of the Board of Health inspected last week 3,788 tenement-houses, containing 34,958 families. They prescribed for 3,246 sick persons who were too poor to pay for medical treatment. Of these, 2,062 were suffering from diarrhœal diseases, and 48 from contagious diseases.

Dr. H. C. Coe, of this city, recently performed laparotomy in a case of abdominal pregnancy at term, and cæsarean section in another case of dystocia. Both cases had a successful termination.

Cincinnati has now a public medical library connected with the Cincinnati Hospital. It is supported by fees from students. The library already has 7,000 volumes.

Fuchsin is found by Dr. Geo. T. Elliott to be a very useful remedy in Paget's disease.

A Dog Hospital and Dog Clinic are to be established in connection with the University of Pennsylvania. We learn that "on the first floor the commodious clinic-room will open into the largest apartment, that for the non-contagious cases. At either side of the latter will be the mange and the distemper wards, both being separated from the clinic-room by heavy brick partitions, the communications with all other parts of the building from these wards being effected only by going outside and around."

The Death-rate of the Hot Week.—The number of deaths recorded during the last week in July, in New York City, was 1,434. Estimating the population at 1,832,473, the death-rate was 40.83 against 30.80 for the previous week. The average for the five years since 1886, for the corresponding period, was 28.33. There were 773 deaths of children under five years, against 647 during the previous week. The deaths resulting from contagious diseases were: Typhoid, 17; scarlet fever, 8; measles, 22; diphtheria, 27; small-pox, 1. The principal causes of the other deaths were: Sunstroke, 90, as against 2 for the week previous; whooping-cough, 11; malarial fever, 7; diarrhœa, 391—355 being children under five years; heart disease, 58; croup, 10; bronchitis, 25; pneumonia, 68; phthisis, 95; Bright's disease, 53; violence, 47; and miscellaneous, 592. There were 290 deaths in public institutions, and 985 among the tenements.

Questions Given at the Examination for the Paris Doctorate.—The following, set at the recent examination for the M.D. Paris, will give some idea of what will be required for a Paris degree.

Anatomy (Oral).—What is the prostato-peritoneal aponeurosis? How is it constituted? What is the nerve of the third pair? What are the relations of the popliteal artery? What position does the femoral vein occupy in relation to the artery and the nerve? What is the course of the internal saphena vein? How does it act in the triangle of Scarpa? What is the nerve of the fifth pair? What are the relations between the arteries and the veins of the bend of the elbow?

Medicine.—Give the indications and counter-indications of digitalis? Describe the symptoms of measles? Describe the symptoms of internal strangulation? What do you know about purulent pleurisies? What is gonorrhœal rheumatism? What do you know of cirrhosis of the liver? What are the signs and causes of hydro-pneumothorax? What is phlegmasia dolens? What are the signs of aortic insufficiency? What is Cheyne-Stokes respiration? What are the signs of phthisis? What are the complications of diabetes?—*Medical Press.*

A New Method of Skin-Grafting.—This is thus described by its originator, Ereberto Aievoli: An animal with well-developed testes is castrated. The organs are washed in the usual salt solution and then cut in thin sections, which are placed in a salt solution. The granulation surface, after being cleaned, is covered with small pieces of the testicle, these being placed one or two centimetres apart. Antiseptic dressing. Good results are claimed which Aievoli thinks are due to the marked biological activity of the cells implanted. In experimentation he used sections of the salivary and mammary glands and the testes.

American Pediatric Society.—The next annual meeting of this society will be held at some summer resort near New York during the latter part of May, 1893. The President of the Society is Dr. A. D. Blackader, of Montreal, Canada; Secretary, Dr. Samuel S. Adams, 1632 K Street, N. W., Washington, D.C.

Society Reports.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, held at the Fort Griswold House, New London, Conn., July 19, 1892.

GORHAM BACON, M.D., OF NEW YORK, PRESIDENT, IN THE CHAIR.

THE Society was called to order by the President.

Mastoid Disease.—DR. OREN D. POMEROY, of New York, reported seven cases of mastoid disease exhibiting somewhat extensive carious processes.

CASE I.—J. W——, aged nineteen. Two years before admission he had a post-aural abscess, which was incised, and a few months later the mastoid was freely opened and carious bone removed. On entering the hospital the mastoid opening was nearly closed and the middle ear was suppurating. There was a swelling below the auricle, red, painful, and preventing free movement of the jaw; pressure on this part evacuated pus from the tympanum. Two days later the patient was etherized and the granulations in the tympanum were removed by the curette. An extension of the mastoid incision opened into a large cavity that seemed to include the mastoid and tympanum. A large quantity of pus was evacuated by syringing. Temperature in the evening, 103.6° F. The next day the temperature was 99° F. Within two days an abscess in front of the velum on the left side was opened. This showed no apparent communication with the ear cavity. After two weeks the discharge became much less, and the carious cavity showed signs of filling up with healthy tissue. The abscess in the throat was probably due to the ear trouble.

CASE II.—M. G——, aged thirty-four. Two months before admission he had acute suppurative otitis in the left ear, with mastoid periostitis, for which Wilde's incision was done. There was an opening in the mastoid three-fourths of an inch deep, into which the little finger could be thrust, at the bottom of which pulsation was apparently felt. The meatus was filled with dried epithelium and pus. There was elevation of temperature from rheumatism in the left hip-joint. The mastoid cavity was cleaned out and packed with iodoform gauze, and large doses of iodide of potassium were given. A few days subsequently some easily detachable bits of carious bone were removed with curette and gouge. The temperature at this time was 103° F., but this was reduced by phenacetine. Stimulants were freely used, and the patient became much better and was able to walk about the wards. A month later pieces of carious bone were removed by the bone curette and gouge. Other portions were washed out by the syringe. Considerable granulation material and a cheesy substance were also removed. The part was dressed with iodoform gauze after irrigation with bichloride solution. The patient was discharged two months after admission, much improved.

CASE III.—T. S——, aged sixteen. Came into the hospital with an acute suppurative otitis media of both ears. Six days later a Wilde's incision was done on the left mastoid. The discharge continued from each ear when he left the hospital, some weeks later It was seven months after this that he came under the author's care for the first time. Over the left mastoid was a small aperture leading into a large carious cavity, which included the mastoid and tympanum. This opening was enlarged by a stout knife, so that the finger could be introduced into the mastoid cavity. Dead bone and granulations were found. On syringing, a soft, flocculent material, resembling broken-down brain-substance, was removed in large quantities. The opening in the mastoid was more than an inch in depth. Antiseptic irrigation was practised, and cotton smeared with vaseline, 5,000 parts, and bichloride, 1 part, was applied to the wound. After three weeks granulations and small bits of bone were removed by the curette. An abscess subsequently appeared above the meatus and communicating with it. This was opened and found not to communicate with dead bone. It was treated antiseptically and by a compress, and gradually the mastoid closed and the discharge from the ear nearly ceased.

The right ear in the meantime had filled with granulations, which were removed with the curette. Pressure on the mastoid caused pus to exude from the meatus, and a Wilde's incision was therefore made in the expectation of finding an opening in the mastoid, but none was found. The wound was kept open by a cotton tent. A month later there was an opening into the mastoid, and two or three considerable masses of dead bone were drawn out with the artery forceps. This left an enormous cavity which seemed to include the tympanum. Polypi were also removed. There was much hemorrhage. Antiseptic irrigation was practised, and vaseline and bichloride on cotton was applied. Since this time granulations and bits of dead bone have been removed. The external wound has now closed with considerable sinking, and the ear has almost ceased discharging.

CASE IV.—A. W——, aged two, had suppurative otitis of the left ear dating back five months. The author first saw her November, 1890, when the tympanum was full of polypi. There was a large carious opening in the mastoid, which was filled with granulation. Small bits of carious bone and a cheesy-looking detritus were removed, and in a few days the patient was much improved. After another month more granulations were removed and some dead bone. Four months later the mastoid opening was closed with considerable sinking. The discharge from the ear diminished after each operation.

CASE V.—J. S——, aged four months, had a swelling behind the left ear of four days' duration, with a discharge from the ear for one month. A Wilde's incision was made and an opening into the antrum found. After a few days a probe was passed in one and one-half inch in the direction of the tympanum, touching bone. This opening was enlarged by the drill and kept clear by syringing with an antiseptic solution. The patient was brought very irregularly, and the treatment was not carried out intelligently, and the child died two months later with brain symptoms.

CASE VI.—A. P——, Italian, aged forty-two, had an otitis media suppurating since three months, with a swelling over the mastoid. The latter was at once incised, and a handle of a scalpel could be thrust through an opening in the cells which seemed to include the tympanum in its area Antiseptic irrigation was practised for some weeks. Granulations were removed from the mastoid. Later there was considerable œdematous swelling about the mastoid, which subsided in a few days, and the temperature became normal. He had several attacks of severe headache, which were relieved by quinine and bromides. More granulations and dead bone were removed, and the next day the patient was better. Soon after this he became offended and made a serious attack on the nurse. He was then sent to the New York Insane Asylum to be examined as to his mental condition, but was soon discharged. He has recently been heard from, and the ear symptoms are not urgent.

CASE VII.—A. P——, aged forty-two, had a suppurative otitis media on the left side, of one week's duration, and a painful swelling over the mastoid since two weeks. Pus was evacuated by a Wilde's incision. A large opening was found in the mastoid extending inward one and one-quarter inch from the surface. After four weeks of treatment by irrigation the external wound was nearly closed. but a sequestrum of bone was found. There was also apparently some cellulitis of the adjoining soft parts. The opening was enlarged and more dead bone removed. After this there was decided improvement, and the patient disappeared from observation.

In these cases no effort was made to remove all the dead bone, but whatever was loose or readily detachable

was taken away. Adequate antiseptic drainage was carefully looked after, and the vital energies were kept up by stimulants, tonics, food, and proper nursing.

It was strange that only one of these cases resulted fatally, when it is known that any considerable quantity of dead bone in the vicinity of the brain may induce fatal cerebral disease. The author did not think it proper to attempt the removal of dead bone where the meninges are in danger of being encroached upon.

Craniometric Studies in Relation to Aural Anatomy.—Dr. B. Alexander Randall, of Philadelphia, read a paper with this title. He referred to the numerous careful studies of the temporal bone made with special relation to operation, and the conflicting results of Kormer and Schultzke as to a relation between the cranial index, and the dangerous position of the lateral sinus and the middle cerebral fossa. Recognizing from the first the need of more extensive examinations, he had been accumulating data bearing on the matter, and offered now a preliminary report, principally to secure criticism of his methods. Only 122 skulls, 73 broad-headed, 33 long-headed, and 16 medium in index, were used in the tabulation, and the only clear showing was that maximum or minimum dimensions might be found on either side and in any form of skull. The belief in the presence of greater danger on the right side and in the brachycephalic skull received slight confirmation, the cerebral fossa being actually more often lower on the left. But no deductions, he held, should be attempted from so small a series of examinations, since any indications are probably worthless which are derived from less than one thousand skull measurements.

Otitis Media and Optic Neuritis.—Dr. Charles J. Kipp, of Newark, N. J., reported a case of purulent inflammation of the middle ear, with double optic neuritis and other symptoms of intracranial lesion, but without tenderness of the mastoid process, in which the opening of the mastoid cells was followed by rapid subsidence of the optic neuritis and cure of the disease. Particular attention was called to the absence of tenderness over the mastoid even on percussion, and to the desirability of repeated ophthalmoscopic examination in prolonged middle-ear disease.

Mastoid Cases.—Dr. C. J. Blake, of Boston, reported a number of cases. Of twenty-five patients with mastoid congestion and inflammation seen in the first six months of this year, three were treated by continuous cold coil with excellent effect. The remaining twenty-two cases came to operation at various stages of the mastoid disease, and with various complications. Two cases died, one on the ninth day, complicated with pneumonia, and the other on the tenth day, with meningitis from extension of the suppurative process from the middle ear through the tegmen tympani.

Basilar Meningitis Occurring in a Case of Chronic Purulent Otitis Media.—Dr. H. Knapp, of New York, reported the case of a healthy-looking man, aged thirty-five years. About middle of April, 1892, he began to complain of headache apparently due to neuralgia. This, however, was succeeded by slight elevation of temperature, but no change in the pulse and no tenderness over the mastoid. The pupils were normal. By the end of April there was drowsiness with nervous movements of the hands. Meningitis dependent upon aural disease was diagnosed by the attending physician. The patient was seen by two prominent neurologists who diagnosed cranial abscess from ear disease. The speaker saw the case May 3d. There had been discharge from the right ear for three years, which had ceased during the previous week. Temperature, 102.2° F. Headache, stupor, incoherent, difficult speech, and delirium were present. The pupils and fundus were normal, and there was no painful spot on percussion of skull. The diagnosis was concurred in and operation urged. This was done the next day. The mastoid was found sclerosed throughout. The superficial portion of the bone presented some evidences of disease, but the deeper the bone was exposed, the healthier it appeared. The operation was then suspended. The patient continued to sink, and died a few days later. The autopsy showed marked evidences of basilar meningitis. The lungs were then examined, and distinct evidences of pulmonary tuberculosis found. The patient had presented no symptoms suggesting examination of the lungs, and all the indications pointed to cranial suppuration following aural disease.

Pyæmia Following Acute Suppurative Otitis.—Dr. J. B. Emerson, of New York, reported the case of a woman, twenty-four years of age, who was admitted to hospital with a free purulent discharge from the ear, but no special tenderness over mastoid, no redness, and no œdema. The temperature for the first six days varied between 101° and 102° F., at the end of which time there was a chill and the evening temperature rose to 105° F., pulse, 125. There was no pain, except in the back of the neck, very little tenderness over the mastoid and left side of head, but no redness or œdema over mastoid. The ear was discharging profusely. The patient's condition continued about the same for five days, when the evening temperature reached 105.4° F. There was still no redness, œdema, or tenderness over the mastoid, and the discharge from the ear was free. The general condition of the patient continued to improve, but an abscess developed over the right sterno-clavicular articulation. Later a second collection of pus formed over the sternum. This was opened, but soon after a swelling formed over the left side of the neck. A few days later an incision was made into the swelling, and pus was found at a depth of one and a half inch. No direct communication with the mastoid could be found. Following this the patient slowly and steadily improved, and was discharged after a course of treatment extending over a period of four months.

Mastoid Operation.—Dr. T. Y. Sutphen, of Newark, N. J., said that on March 17, 1892, he was called to see Miss B. K——, aged sixteen. There had been chronic otitis media of the left ear for several years. For a few days there had been intense pain and a temperature of 105° F., but no sign of mastoid trouble other than the pain. The next day there were general septicæmic symptoms with chills, alterations in temperature, and vomiting. A hard swelling beneath the sterno-cleido-mastoid muscle was discovered. May 22d, the mastoid was opened, but there was only a drop or two of purulent fluid. The condition of the patient continued very unfavorable until May 30th, when pus began to flow freely from the mastoid wound. The temperature then fell to 99° F., and the patient made a rapid recovery.

Mastoid Disease Following an Operation for the Removal of Adenoid Vegetations.—Dr. Gorham Bacon, of New York, reported the case of a patient, aged thirty, who said that a physician had a week before removed adenoid vegetation from the naso-pharynx, by means of the index-finger, and completed the operation the following day with forceps. She had a subacute pharyngitis at the time. Two days after the operation she had severe pain in the right ear, and this was followed by a mucopurulent discharge on the day of admission to hospital. She was immediately put to bed, the Leiter coil applied, and the ear douched frequently with a warm boracic acid solution. Under this treatment the mastoid symptoms soon disappeared. A week later a periosteal abscess on the right side was opened and about a drachm of pus escaped. An incision in a similar swelling on the left side gave a negative result. The patient made a good recovery, and at no time did the temperature go above 100° F. The case was reported because the writer had not seen any mention made of acute otitis media and mastoid disease following the operation for removal of adenoid vegetations. It is possible, however, that the carbolic acid solution which the patient was advised to syringe through the anterior nares, by the physician, before she came under the author's care, might have had something to do with the etiology of the disease.

Antiseptic Solutions in Purulent Middle-ear Disease.—Dr. Samuel Theobald, of Baltimore, read a paper on "The Value of Weak Solutions of Bichloride of Mercury in the Treatment of Otitis Media Suppurativa." He stated that boracic acid in fifteen-grain solution was still, as it has been for some years, his first choice in the treatment of all cases of recent, and in most cases of chronic, otorrhœa. Boracic acid, however, occasionally fails to accomplish what is expected of it, and in exceptional instances aggravates rather than lessens the inflammation. It was in these cases that the speaker had recently used, with very good effect, weak solutions (usually 1 to 8,000) of mercuric bichloride. The ear is simply syringed with the solution. Unlike some who have recommended the use of this agent in otorrhœa, he had not usually found it necessary to repeat the syringing more than once in twenty-four hours. Notes of several cases were given in which a prompt arrest of suppuration and closure of the perforation in the tympanic membrane followed the employment of the bichloride solution after boracic acid had been used without effect.

Wound of the Lateral Sinus.—Dr. D. B. St. John Roosa, of New York, reported a case in which a wound of the lateral sinus, occurring in the course of a mastoid operation, was followed by septicæmia, with subsequent recovery. The speaker remarked that there had been a number of cases reported in which the sinus had been wounded during operation, but that, so far as he was aware, death had in no instance resulted from this accident. The patient, a young lady aged twenty-three, had for years suffered from recurrent attacks of suppuration of the left ear. It was thought that the mastoid was probably in a carious condition, and it was decided to open it, the drill being used. As soon as the bone was perforated the drill dropped into a large cavity, and the removal of the instrument was followed by a gush of venous blood which could not be checked by ordinary means. It was believed that the lateral sinus had been perforated. The wound was plugged with iodoform gauze. Four days later, when the wound was dressed, there was no trouble from bleeding. Symptoms of septicæmia then set in, but after two months of expectant treatment the patient made a complete recovery.

Remarkable Improvement in Hearing Following Removal of the Stapes.—Dr. F. L. Jack, of Boston, said that he had recently operated on a case of chronic suppurative otitis in a girl aged twelve. After removing portions of the membrana tympani, malleus, and incus, examination showed the head of the stapes to be carious, and it was decided to remove the bone. Previous to operation there was very little hearing in the affected ear. On the following morning the hearing was much better, and this fact suggested the possibility of good results from the removal of the stapes. Previous to this the speaker had operated on two cases of chronic non-suppurative middle ear inflammation, by removal of the drum membrane, malleus, and incus. The results, as regards hearing, were not satisfactory. Removal of the stapes is much better in its results, and in the author's experience there had been no inflammatory reaction whatever. The method of operating was then described. Sixteen cases were reported in detail, giving the results of tests for hearing before and after operation. Two of the cases were presented to the Society for examination. The effect of the operation on the hearing, as tested by the watch, in some was not marked in either way, in others there seemed to be a slight loss, and in others again a slight gain. But the result which gave to the operation its importance was the marked improvement in hearing the human voice which was thereby accomplished. If persons who had heretofore heard only with difficulty, could be made to hear with ease, the operation by which this was accomplished ought certainly to be worthy of consideration. As to the reason why this effect is produced by the operation, the speaker had no theory to offer other than the simple supposition that it was by the removal of a mechanical obstruction to the sound-waves.

Middle ear Operations.—Dr. C. J. Blake, of Boston, presented a communication with this title. The history of the surgical treatment of middle ear disease was first briefly referred to, and it was shown that it had been definitely progressive.

In chronic non-suppurative diseases of the middle ear, where surgical interference is determined upon on account of obstruction to sound transmission through ossicular change, the removal of the incus or malleus may be considered merely incidental, since the stapes is the important element. Various procedures for the mobilization of the stapes have been proposed and practised, but the removal of the stapes has until recently been left out of serious consideration. The justifiability of this procedure is to be premised from the fact that the stapes is especially liable to be tied down by the reduplications found in about eighty per cent. of normal ears.

The writer's experience in this matter consisted in a series of experiments in various cases, beginning with the observations having reference to the diagnostic value of high musical notes (1873), extending up to the present time, and including operations in the following sequence: 1. Excision of the posterior segment of the membrana tympani, allowing the sound-waves to fall directly upon the stapes. 2. Formation of a flap from the posterior segment of the membrana tympani, and attachment of it to the descending process of the incus, for the purpose of transmitting the vibrations of the membrane directly to that bone. 3. Division of the incudo-stapedal articulation through a small triangular opening in the membrana tympani. 4. Attachment of a flap from the posterior segment of the membrana tympani to the head of the stapes, the incus being either wanting or removed. 5. Division of the incudo-stapedal articulation in case of existing perforation of the membrana tympani, division of the stapedius muscle and of numerous folds of adhesions. 6. Removal of the stapes itself.

Mobilization of the stapes, including stapedenotomy and division of adhesion, is of value in cases resulting from suppurative disease; is of comparatively little value in the chronic non-suppurative disease of the middle ear. For the improvement of hearing and the relief of tinnitus in the severe cases of chronic non-suppurative diseases of the middle ear, the disarticulation and removal of the stapes is likely to be of more lasting benefit than removal of the incus, or of the malleus and incus. The speaker would not hesitate, in the light of present experience, to recommend stapedectomy in cases where he had previously proposed dividing the articulation of the incus and stapes and tenotomy of the stapedius muscle.

The operation varies in difficulty in individual cases, but is more easily done in chronic non-suppurative cases than in those in which the fixation of the stapes is an incident of a long continued suppurative process.

A Case of Operation for Catarrhal Deafness.—Dr. B. Alexander Randall, of Philadelphia, reported a case of excision of the drum membrane and malleus for catarrhal deafness, followed by suppuration, mastoid empyema, and burrowing abscess of the neck. No reaction followed till the fifth day, when high fever began with severe pain and profuse muco-purulent discharge. This gradually lessened under treatment, but in about four weeks pain and swelling of the occiput, of the mastoid, and at the angle of the jaw, gave evidence of the mastoid empyema breaking into the digastric fossa. The usual incision was made over the mastoid, pus was evacuated from the digastric fossa; the neck abscess beyond the bone sinus was scraped, and the outer surface of the mastoid was trephined in the usual manner, the antrum being freely opened. On irrigation, the fluid passed into the canal at first, then found its way into the pharynx by some lower opening, the temperature fluctuated greatly during the following fortnight, and there was oculo-motor paresis, diplopia, and some mental aberration suggestive

of intracranial abscess. A good recovery was ultimately made, but at no time was there any improvement of the hearing to compensate in the least for the suffering. While the severe symptoms might possibly be ascribed to an attack of influenza, it is much more probable that the incus, which had been displaced upward, clogged the exit of the antrum and induced the empyema. This would furnish a strong indication for the removal of the incus in any such operation, which even then may be followed by negative or unfortunate results.

Exostosis of the External Auditory Meatus.—Dr. D. B. St. John Roosa, of New York, reported the case of a woman aged forty-six years, who for twenty-one years had had impairment of hearing and tinnitus in the right ear, and pain in both ears at times. Examination showed the external auditory canal to be almost completely closed by a bony growth at the junction of the osseous and cartilaginous portion. She could hear the watch only on contact. The mass sprang from the posterior wall, and left a small space between it and the anterior wall. On operation it proved to be a very thin plate of bone, and was removed by the chisel without difficulty. The patient did well, and the hearing distance for the watch went up from contact to $\frac{1}{40}$.

Dr. C. J. Blake, of Boston, stated that in two different families he had seen multiple exostoses occurring in three generations, grandfather, father, and son.

Dr R. A. Reeve, of Toronto, reported a case of exostosis of the meatus in which the special indication for operation was that the growth had become so large as to press upon the tissues of the opposite wall of the canal, causing intense suffering.

Dr. E. E. Holt, of Portland, Me., exhibited an ear bitten off by a horse, and made a brief report of the case.

Dr. C. J. Blake, of Boston, exhibited the plans for the new Aural building of the Massachusetts Charitable Eye and Ear Infirmary.

Election of Officers.—*President*, Dr. Gorham Bacon, of New York; *Vice President*, Dr. Huntington Richards, of Des Moines, Ia.; *Secretary and Treasurer*, Dr. J. B. Vermyne, of New Bedford, Mass.; *Member of Executive Committee of Congress of American Physicians and Surgeons*, Dr. William H. Carmalt, of New Haven, alternate, Dr. F. B. Loring, of Washington.

BRITISH MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, held at Nottingham, July 26, 27, 28, and 29, 1892.

Abstracts of Addresses Delivered at the General Sessions.

(Condensed from advance sheets of the *British Medical Journal*.)

The President's Address.—Mr. Joseph White took for the subject of his presidential address a review of the development of the work of the British Medical Association and of British Medicine and Surgery since the last Nottingham meeting. He began with a description of Nottingham as a very clean town, for a manufacturing one, in some parts rather picturesque, and not unhealthy. The death-rate of the town had fallen steadily from 1850, when it was 28 per 1,000, to the present, when it was but 17.9, being the third lowest of the twenty-seven largest towns in England.

The last time the British Medical Association met at Nottingham was in 1857, and the progress since made by it was very striking. The number of members at that time was 2,065, while now it was more than 14,000. It had then no sections, its branches were confined within the limits of the southern half of Great Britain, and one small room sufficed for the accommodation of those taking part in the meeting.

The speaker then dwelt upon the advances in surgery and in medicine which had been made during the past thirty-five years, not only in Great Britain but in other countries as well, and concluded by expressing the belief that the British Medical Association was specially fitted—by reason of its organization, with branches extending over nearly every part of the world, with almost every climate as its field of work, and with thousands of members all engaged in the same pursuits, all animated by the same aims and desires for the same kind of knowledge—for developing in the highest possible way the fruits of that combined work on which he believed the future of medicine to depend in great measure.

Surgery.—Dr William H. Hingston, of Montreal, delivered the address, taking for his title, "Synthesis in Surgery." The speaker devoted a large part of his discourse to the climate and prevalent diseases of Canada, and to a description of domestic surgery as practised by the Indians of the Dominion, from whom he thought more civilized people might learn not a little. "If in the depths of the forest an Indian breaks his leg or arm, splints of softest material are at once improvised. Straight branches are cut, of uniform length and thickness. These are lined with down-like moss, or scrapings or shavings of wood, or with fine twigs interlarded with leaves, if in summer; or with the curled up leaves of the evergreen cedar or hemlock, if in winter; and the whole is surrounded with withes of willow or osier, or young birch. Sometimes it is the soft but sufficiently unyielding bark of the poplar or the bass-wood. Sometimes, when near the marshy margin of our lakes or rivers, the wounded limb is afforded support with wild hay or reeds of uniform length and thickness. To carry a patient to his wigwam or to an encampment, a stretcher is quickly made of four young saplings, interwoven at their upper ends, and on this elastic, springy couch the injured man is borne away by his companions. When there are but two persons, and an accident of this nature happens to one of them, two young trees of birch or beech, or hickory are used Their tops are allowed to remain to aid in diminishing the jolting caused by the inequalities of the ground. A couple of cross bars preserve the saplings in position, and the bark of the elm or birch, cut into broad bands and joined to either side, forms an even bed. In this way an injured man is brought by his companion to a settlement, and often it has been found, on arrival, that the fractured bones are firmly united, and the limb is whole again."

The surgeon of practical mind learns, like the aborigines, to make use of whatever is nearest to his hand when scientifically constructed instruments are wanting, and often practice gives him such skill in the use of the former that he retains them in preference to any of special and complicated construction. Some years ago, Dr. Hingston said, he was present at a meeting of a medical society in one of the Western United States. A gentleman from one of the large centres had exhibited an instrument for removing foreign bodies from the nose. He extolled its advantages, was applauded, and everything promised well. A smile, however, came across the faces of many present when a small, nervous man advanced somewhat briskly to the platform. His style was sharp, his language terse, and personal pronouns were used most sparingly. He commenced somewhat in this fashion: "Mr. President—Much obliged to the gentleman from the city. Long distance for him to come to show us this instrument; long distance for us out here to send for one when wanted. Now, when called to see a child with a cherry or any other kind of stone, or a pea, or a bean, or a bead, or a button in his nose, not going to send all the way to the city for this instrument, and for the professor to come with it—for that's what it means. Can do without both. Wherever there's a boy with something in his nose that has no business to be there, there is sure to be a woman in the neighborhood, and wherever there's a woman there's sure to be a hairpin. Now, with the boy and his nose and something in it and the woman and her hairpin, and a live doctor and his jack-knife, nothing

more is wanted. Now, with the jack-knife, half open, bend the double end, coax this bent end along the roof of the nose, raise the wrist a little, and withdraw with the bent end well down, and if one of the child's toys is there it's safe to come."

Returning from this digression the speaker said he was far from wishing to imply that the practice of surgery in Canada was in general primitive. On the contrary, in the larger Canadian cities surgery in every department is pretty much what it is in the more favored cities of Europe, in the way both of refined diagnosis and of dexterous and courageous operation. There are, indeed, surgical pioneers there, for "the tongue and lower jaw were together first removed in Canada; the innominate and the gluteal arteries were first ligatured in Canada; and the credit of the first nephrectomy, which writers give so generally to Germany, belongs to Canada and to Montreal."

The orator then took up the main part of his address, that to which he had given the name synthesis in surgery. He referred to the subdivision of the surgical art into so many specialties, and the danger resulting therefrom in the narrowing of the specialist's horizon, and in his tendency to take a part for the whole and to give to that part an undue width. The art of surgery is becoming more and more divided into an ever increasing number of special branches, each branch having its respective province, which is sometimes kept too sharply defined by an exaggerated interpretation of its importance. Yet, he maintained, each must ever remain cognate to, and in close relationship with, every other department of the art, for there are no limits or boundaries to their various departments, and a seemingly intimate acquaintance with one and a total nescience of others are crass ignorance of all. He did not wish to be understood as desiring to interfere in any way with the pursuit of any particular course, however narrow it might appear to some, however vast to others. His desire was simply to *extend* the horizon of each, not to narrow it, and to show that all branches of our art are cognate to each other.

In concluding, the speaker referred to the necessity to a candidate for admission to the study of surgery of a liberal education. He would not do away with the classics in the preliminary studies, but would demand an education which was more than classical. Physicians and surgeons had always been among the most learned and the best informed. But at the present day the difficulty of preserving that distinction is greater than formerly. Education, at one time confined to the few, is now possessed by the many, and while the separation of professions and division of labor tend to the perfection of art, says Dr. Copleston, yet, he adds, "although the art itself is advanced by this concentration of mind in its service, the individual who is confined to it goes back."

Medicine.—The General Address in Medicine was delivered by DR. JAMES CUMING, of Belfast, who began by a reference to the relative decrease of learning in the medical profession. Bacon had said that there was greater honor to divinity and more profit to law, but the palm of learning must be awarded to physicians. To-day, the speaker said, while we have lost in respect of learning, we cannot be said to have gained much upon our sister professions in respect of honor or of profit. Yet at no period of the world's history has medicine been more assiduously cultivated, never have its ranks been filled by so many able and energetic workers, and at no period have its claims to public usefulness been capable of being so triumphantly vindicated. He believed that the remedy for this state of affairs was to be found in less devotion on the part of the medical student to the study of chemistry, botany, and natural philosophy. These sciences have themselves grown to such proportions that no one man, even though giving his whole time to it, can hope to master any one of them. "It may be urged that the study of the ancillary sciences, as they have sometimes been called, is of high importance to the discipline of the intellect, and tends to develop the habit and the power of careful and accurate observation; and this may be admitted in the fullest and most ungrudging manner. But the powers of the average human intellect are far from illimitable, the capacity of attention is bounded, and the sum of mental energy requires to be carefully husbanded, to be directed in the right channels, and not to be allowed or compelled to dissipate itself in useless effort." The speaker believed that there were other subjects more closely identified with medical science which would afford abundant scope for mental discipline, while at the same time serving as a good foundation upon which to erect the superstructure of practical medical knowledge.

The recent advances in bacteriology were then dwelt upon, the orator taking the view that Metschnikoff's theory should be accepted. He believed that certain cells possess the power of attacking and destroying infective microbes within the body, although he did not deny that there might be much of weight in Buchner's views regarding the importance of antibiotic fluids in the blood.

Dr. Cuming next referred to the increase in nervous diseases and insanity, an increase which statistics showed to be very real, notwithstanding that it had been denied by some. He thought that this pointed to the necessity of a study of psychology, without an acquaintance with the methods and problems of which it is impossible to observe and to describe adequately the phenomena of morbid mental states. It was gratifying, therefore, to find how great an amount of research was now being conducted on the subject of experimental psychology. In this direction much of the best work had been done in the Leipsic Psychological Laboratory, by and under the direction of Wundt, but kindred investigations are being made by various observers elsewhere. The researches on the intensity and the time relations of sensation and of motor response to stimuli are of the highest interest. They have enabled us to ascertain the time occupied by mental acts, by the reproduction of impressions, by acts of association, and by logical judgments. The amount and quality of work done in this direction justify the hope that psychology, as a natural science, will take its place beside physiology, and that the physical basis of mental activity will be more and more understood and elucidated.

Returning again, in closing, to the problem of the preliminary education of the medical student, he said that it was to be regretted that the study of the old humanities must be curtailed, and must even in some measure disappear from medical education. "Greek seems doomed past recall, and it will, perhaps, be possible to say, at some future day of the medical profession, as Petrarch said of Italy in the fourteenth century, that it did not contain more than ten persons who could appreciate Homer. And yet, in putting aside Greek, medical men will miss some of the finest products of the human intellect, moulded in the most perfect form. . . .

"Latin will make a harder fight to maintain its place, and will probably succeed in retaining it. If it should fail, it will be impossible not to feel a profound sense of compassion for the physicians of the future, if they are never to be admitted to the simple feasts at the Sabine farm, at which educated men have been charmed guests for so many generations; or if they are never to feel the beauty and finish of the hexameters of Virgil. . . .

"The pursuit of literature is everywhere being regarded as less necessary, and from a utilitarian point of view it is impossible to give more than a passing regret to those branches of learning which have so long been regarded as the stamp and evidence of culture. What with unconscious irony are called the paying subjects are brought more and more prominently forward in general education, and those studies which bear on professional training will ultimately prevail to the comparative exclusion of all others."

Bacteriology.—Dr. G. Sims Woodhead, in his address, took up first the subject of "Antitoxins and their Influence in the Cure of Disease," a subject on which so much confusion exists in the minds of many. It has been found, in the case of hog-cholera for example, that the serum from an animal vaccinated against this disease allows of a most luxuriant growth of the hog-cholera organism, and that it certainly exerts no antitoxin action when injected into an animal suffering from the disease. On the other hand, when the serum from a vaccinated animal is injected from time to time into the circulation of a non-vaccinated animal, which is some time afterward inoculated with hog-cholera virus, it is found that the animal now enjoys a very marked insusceptibility to the disease, while the serum of animals not previously rendered immune to the disease, when injected into non-vaccinated animals, exerts no protective effect, the disease being developed just as in animals previously unexperimented upon.

"If, now, we consider that this serum from vaccinated animals serves as an excellent cultivating medium for the growth of micro-organism of hog-cholera, as, too, we find that when sterilized products of a culture of hog-cholera bacillus or the blood taken from an immune animal do not interfere with the special poison when introduced simultaneously into the circulation, it must be concluded that such sterile product does not act directly either on the bacillus or on the poison produced by the bacillus; on the other hand, we find that this same substance introduced into the circulation of the animal undoubtedly exerts a certain protective influence, so that we are compelled to the conclusion that this serum—or rather some body present in it—must act directly on the protoplasm of the cells of the body. Metschnikoff argues that it must act as a specific stimulant, for it is generally accepted that there is a specific protection for most specific diseases. It must be held, too, that a modification of all the cells of the body with which this poison can come in contact may take place, for all these cells are equally liable to be attacked by organisms."

Should it be definitely proved, however, that antitoxins are formed as the result of the action of certain bacteria on the tissues and fluids of the body, this part could prove of little practical value in the treatment of disease, for very large quantities of the blood or serum from immunized animals have to be used in order to obtain the results desired, and it is difficult to imagine how it would be possible to obtain sufficient of the antitoxin from living animals, however vaccinated; while the risks to patients would be so great that such treatment would be unjustifiable.

This is, of course, different from what the speaker called the process of acclimatization. According to this acclimatization theory various cells and tissues of the body become so accustomed to the presence of certain poisons when administered in small but gradually increasing quantities at definite intervals, that when large doses are actually formed within the body, the tissue-cells are still able to react, to carry on their phagocytic functions, and thus to treat pathogenic organisms as mere saprophytes.

The importance of bacteriological chemistry was insisted upon, and the nature of the work thus far done was exemplified in the case of diphtheria, a disease in which, the speaker held, owing to the bacteriologico-chemical methods which have been imported into its study, we not only recognize with a moderate degree of certainty that we have to do with a specific organism, but also have learned how it acts.

A New Cause of Measles.—An English health officer recently received the following note from one of the residents of his district: "Dear sir, I beg to tell you that my child aged eight months is suffering of measles as required by Act of Parliament."

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Twenty-sixth Annual Meeting, held at Atlantic City, June 28 and 29, 1892.

Elias J. Marsh, M.D., of Paterson, President.

Reports of Committees.—The Society was welcomed to the City of Sanitation by the Mayor, Dr. Willard Wright, and on the part of the local profession by Dr. Boardman Reed, after which reports of various committees were read, including that of the Standing Committee.

Medical History of New Jersey for 1891.—Dr. D. C. English, Chairman of this committee, stated, in his summary of the reports received from physicians in different counties of the State, that la grippe seemed to have become a regular visitor. It had been attended by a greater fatality, especially among the aged, in some of the counties than in previous years, and in some had often been complicated by pneumonia. Dr. Stickler had reported one case of la grippe in which the pharynx was covered with a fibrinous membrane. Diphtheria had been less prevalent. Rubeola and rotheln were said to have prevailed together, the one not giving immunity against the other, thus proving their separate existence. There had been eighty cases of variola in Newark, several in Passaic. Dr. William Pierson, of Orange, had reported a case of carcinoma of the kidney weighing forty-three pounds.

Among the questions which the committee had sent out was one asking, "What have you found the best antiseptic in derangement of the stomach, diarrhœa, and typhoid?" The answers had been multitudinous, but the remedies oftenest mentioned were, in order of frequency, salol, bismuth, carbolic acid and iodine, sulpho-carbolates, creosote, naphthalin, listerine, calomel, etc. To the question, "What is your most usual treatment of peritonitis?" most replied, "Opium as recommended by Alonzo Clark;" some, "salines;" others, "mixed treatment." About twenty cases of sudden death during pneumonia had been reported. In reply to the question, "What has been the value of hyoscin and its compounds in insomnia?" contradictory reports had been received. The drug seemed most useful in sleeplessness attended with choreic movements or excitement. The committee queried, for the possible benefit of the younger men, whether new drugs and new combinations suggested by enterprising manufacturers were not too often tried to the discredit of older and more reliable remedies.

The President's Annual Address.—Dr. Marsh chose for the subject of his annual address, "Longevity: More particularly the Natural Duration of Life in Man." The subject had been written upon to some extent in ancient and mediæval times, and had recently received not a little attention from scientists. The natural duration of life, excluding the question of external influences, had not varied essentially from the time of reliable history. Cicero evidently considered seventy years an old age. Unless in lower forms of organization, as in cells which propagated by division, the duration of life was limited, and within certain, comparatively speaking, narrow bounds. Buffon believed that the natural life of man and animals was some multiple of the period at which they attained their growth, and the same view had been accepted by Flourens and others, but the period of growth and the multiple given by different writers had not been uniform. Proximately, however, physiology gave man a life of one hundred years. Individual instances in which this period had been considerably exceeded were not unknown, although in many traditional instances of the kind there was room for doubt. The cases of Parr, Desmond, and Jenkins, if entirely reliable, would show the possibility of human life being extended beyond a century and a quarter, and indeed beyond one hundred and fifty years. In army records only about two persons of a million men attained a height of seven feet, yet now and then one reached the extraordinary height of eight feet, so that by analogy it was not improbable that here and there a per-

son reached the great age of one hundred and twenty-five years or more. A physician, member of the Cumberland County Medical Society for seventy-four years, still living, was born in 1792. The English and American censuses of recent years had given a number of cases of centenarians.

By collective investigation on the part of English physicians, undertaken at the suggestion of Professor Humphrey, a list of nearly nine hundred cases of persons of great age, seventy-one above one hundred years, had been published, in many of which the age could be vouched for. In these instances questions had been answered with regard to habits of life, weight, etc.

The following facts were emphasized by the essayist's studies: That a prime requisite of long life was to start with a good inheritance, a body, so to say, which was wound up and sent into the world to run a long period; a body well developed, the organs proportionate; avoidance of excess of food and drink, and of general overstrain, or over-strain of special organs. While the duration of life among physicians had not been of the greatest as compared with other pursuits, yet Dr. Marsh saw no reason why each member of the medical profession might not so live as to attain to the full number of years allotted to man, if his inheritance and early training permitted, and in no other pursuit could one feel more assured of the good will and respect of the community in his last days.

The Society's Library.—The report of Dr. H. Genet Taylor showed a steady growth of the Society's newly begun collection of medical works at Trenton. The committee, which had also had under consideration the question of starting a medical museum, thought it best that no action be taken.

The Doctors and the National Guard.—Dr. Storck, of Camden, offered resolutions, including a vote of thanks, to the Legislature and the Governor, for an act which went to place the Medical Corps of the State militia more nearly on a footing with that of the United States Army. To some this seemed to savor of politics, but a majority voted for the resolutions.

The Gross Monument Fund.—Dr. B. A. Watson made an earnest appeal in behalf of the Samuel Gross Monument Fund, and at his request a committee was appointed representing each county.

The True Pathology of Sudden Death in Acute Pneumonia and the Best Means of Averting It.—Dr. C. F. J. Lehlbach, of Newark, opened the discussion on this subject, which was presented at the last meeting, by reading a paper. Cases with previous disease, such as nephritis and heart lesions, were excluded from the discussion. While citing no new cases with post mortem examination, the author arrived at the conclusion that the most common cause of sudden death in acute pneumonia (usually not occurring until commencement of convalescence) was embolism of the heart and pulmonary artery. Pneumonia seemed to favor thrombosis and embolism. It became obvious, therefore, that whatever preventive means were taken they would have to be general and precautionary. Exertion should be avoided for sometime after convalescence. Ammonia was not only one of the best cardiac stimulants, but it also tended to prevent blood coagulation and the formation of emboli. He recommended the salicylate of ammonia because of its additional efficacy in rheumatic complications. The discussion was participated in by Drs T. R. Chambers, Currier, Rogers, Evans, Condit, Ridge, Neer, and Armstrong, whose remarks were directed chiefly to preventing sudden death.

Dr. Chambers cautioned against the cumulative action of digitalin, others recommended oxygen inhalation, strophanthus, ammonia, etc.

Report of Committee on Dairy Cows.—Dr. H. L. Coit, of Newark, read the report of the committee, which was continued from last year. The importance of the subject was made evident by the statement that over two billion dollars were invested in the dairy business in the United States; four million farmers owned fifteen million cows; over six billion and a half gallons of milk were produced. The reader here showed how rapidly milk deteriorated, the influence thereon of improper food given the cows, and made mention of adulterations. Milk's greatest enemy was bacteria. It appeared that New Jersey's cows were being better cared for, but the greatest evil in the feeding line was the use of brewery waste, which rendered the milk watery, was wanting in certain of the nutrient elements, and likely to ferment early. Other points brought out referred to tubercular cows, cleanliness, etc.

The report was adopted, together with a resolution urging more energetic action on the part of the State Board of Health and Board of Agriculture.

Ethics in New Jersey.—The Committee on Honorary Membership had had before it three names, all of New York doctors, and although it recommended their election, the question was raised whether they belonged to the old or the new code party; or, rather, whether they consulted with irregulars, and as the committee could not answer that question, it was requested to report next year.

After hearing reports from delegates from other States, and from the American Medical Association, by Dr. Johnson, the Third Vice-President, Dr. O. H. Sproul, read his address on

Obstetrical Statistics. — Dr. Sproul had commenced early to keep statistics of his cases, which now included 1,500 consecutive cases of labor at or near term. Vertex presentations, 1,435; breech, 58; shoulder, 7; placenta prævia, 11; puerperal eclampsia, 6; puerperal fever, 2; still-births, 82; forceps, 138; version, 15; craniotomy, 0; rupture of uterus, 1; deaths, 7; excess of males, 199; excess of night deliveries, 132; hour-glass contraction, 2; rupture of perineum, 18.

The author would now use the forceps oftener to shorten labor and relieve suffering. He performed immediate perineorrhaphy. There were a few cases of deformity.

Compression Corset in Cake Breast.—Dr. Chambers presented a corset with rubber cloth front for exercising compression in mammary inflammation which had not proceeded to the stage of abscess. He also presented a rubber bag to draw over the scrotum in acute epididymitis or orchitis, and said it was far superior to poultices, etc., in relieving the pain and swelling.

Dr. Mordecai Price showed a uterus containing a fœtus well advanced.

Election of Officers.—*President*, George Y. Welch, of Passaic; *First Vice-President*, John G. Ryerson; *Second Vice-President*, O. H. Sproul; *Third Vice-President*, William Elmer; *Corresponding Secretary*, E. L. B. Godfrey; *Recording Secretary*, William Pierson; *Treasurer*, Archibald Mercer.

To meet at Spring Lake, fourth Tuesday in June, 1893.

The Treatment of the Status Epilepticus.—Dr. Kernig (*St. Petersburger Med. Wochenschrift*) publishes an account of a method of treating the so-called "status epilepticus," and gives the following particulars of a case treated by this method: A girl in the Obuchoff Hospital in St. Petersburg, after suffering a whole night from almost continuous epileptic convulsions, next morning was unconscious, but without any œdema of the lungs, and with a fairly good pulse. On the convulsions being renewed, a hypodermic injection of 0.02 gramme of hydrochlorate of pilocarpine was given, and 1.5 gramme of camphor in an emulsion. Profuse perspiration followed, and the convulsions immediately ceased, but for an hour pulmonary œdema and collapse seemed imminent. These symptoms, however, passed off, and were followed by sound sleep and a good pulse. The patient was made to lie on her side, to prevent annoyance from the excessive secretion of saliva.

GEORGIA STATE MEDICAL ASSOCIATION.

Forty-third Annual Meeting, held at Columbus, Ga., April 20, 21, and 22, 1892.

DR. G. W. MULLIGAN, OF WASHINGTON, PRESIDENT, IN THE CHAIR.

Ovarian Cyst.—DR. C. M. SPENCE, of Waresboro, gave the history of an interesting ovarian cyst. The patient gave a history of a twin birth five years before the doctor's visit. This was followed in a year by triplets, and then the tumor began to grow in the right ovary. Dr. Spence found the lower extremities filled with water, caused by pressure. The measure of the abdomen was 6½ feet, and from the pubes to the ensiform the distance was 3 feet and 9 inches. A trocar drew seventy quarts of thick straw-colored fluid. Two weeks later twenty-eight quarts of similar fluid was withdrawn, together with a substance that looked like human brains. Two weeks later thirty ounces of fluid was obtained, and ten days later patient had cholera morbus and died.

The Influence of Civilization and Social Life upon Women, as Viewed from a Medical Standpoint.—DR. D. C. HURT, of Columbus, read a paper on this subject. He compared the savage and civilized women of America, claiming the latter's comparatively weak constitution due to their methods of life and dressing. He called on the profession to correct these evils.

The Relation between Skin Diseases and the General Health.—DR. M. B. HUTCHINS, of Atlanta, read a paper with this title. He treated of eczema chiefly, and reached the conclusions that skin diseases are not all blood diseases, and that of the etiology of skin diseases little is as yet known.

The Treatment of Abortion, and Some of the Complications Incident Thereto, was the title of a paper read by DR. W. A. CROW, of Atlanta. He claimed there was a marked tendency to infection in abortion; that consequently all sources of infection should be removed if possible; that all the fœtal membranes and placental tissue should be removed; patient should be kept under observation for two months, to complete involution of the uterus and to build up general health; that the patient should avoid becoming pregnant within following six months.

The Treatment of Pneumonia, with Report of Cases.—DR. H. PERDUE, of Barnesville, read the paper. Fifteen cases of lobar pneumonia were treated without a death by using peroxide of hydrogen. Throughout the stages of congestion and consolidation he gives phenacetine in five-grain doses in connection with whiskey or milk-punch, every four hours, unless the temperature should get below 103° F. Good nursing is an important factor in the management of pneumonia patients. A nutritious liquid diet, such as sweet milk, beef-tea, and palatable broths should be given. In convalescence, stimulating expectorants and tonics are indicated.

"What is Gynecology?" was the title of the paper read by DR. R. R. KIME, of Atlanta. He traced its history to the present time, and showed the prominent part the South had taken in its remarkable progress.

Remittent Fever.—DR. A. C. BLAIN, of Macon, read a paper on this subject. His treatment is with quinine, giving it in morning doses. He thinks a mercurial cathartic, followed by quinine and a mineral acid, will abort attacks, if given early.

The Surgical Treatment of Puerperal Peritonitis.—DR. W. E. S. DAVIS, of Rome, read the paper. The disease results from infection during the puerperal state. When quarts and gallons of pus are removed from the general cavity and recovery follows, he thinks the pus has usually resulted from a local collection which has ruptured into the general cavity, and the operation has been done before sufficient time has elapsed for this amount of pus to result from the septic inflammatory process in the general cavity. This form of disease, localized puerperal peritonitis with pus formation, is amenable to surgical treatment.

"How Shall We Manage the Uterus after Abortion?" was the title of the paper read by DR. K. P. MOORE, of Macon. He emphasized the necessity of cleaning out the cavity of the uterus in cases of abortion, and by so doing it would be the means of preventing some of the troubles incident to an abortion.

Cough: Some of its Causes and Treatment, was the title of a paper read by DR. C. D. ROY, of Atlanta. In regard to treatment, he dwelt on the necessity of removing all sources of irritation in the nose, throat, and larynx. The aim of the physician should be to restore all organs to their normal state.

Some Observations upon Cataract Operations and After-treatment.—DR. A. W. CALHOUN, of Atlanta, read the paper. He reported nine hundred and four operations, and claimed one hundred per cent. of successes since the introduction of cocaine and antiseptics. In regard to age, the number of hard cataracts was as follows: 138 from 25 to 40 years of age; 82 from 40 to 50; 98 from 50 to 60; 157 from 60 to 70; 104 from 70 to 80; 28 from 80 to 90; 11 from 90 to 94.

Gunshot Wound of the Stomach.—DR. A. A. SMITH, of Hawkinsville, read this paper, reporting a case of a negro who had such a wound. The bullet was passed per rectum, the wound healed by primary union, and the patient returned to work one week from date of injury.

Some Practical Points in Reference to Eye-strains, was the title of a paper read by DR. R. O. COTTER, of Macon. He said many troubles, especially headaches of the vertex, temporal, and frontal regions were due to uncorrected errors of refraction.

Plaster of Paris in Surgery, was the title of a paper read by DR. WILLIS F. WESTMORELAND, of Atlanta, illustrating the proper method of applying splints.

Preliminary Observations on the Behavior of Iodine in the Presence of Camphor, Menthol, Thymol, etc.—DR. NUNN, of Savannah, read this valuable paper. The presence of the materials makes iodine soluble; for instance, a mixture of menthol and camphor liquefies, and in this liquid iodine is very soluble.

Eclampsia after Delivery, with Report of Cases.—DR. L. G. HARDMAN, of Harmony Grove, read the paper. Eclampsia frequently occurs, chiefly in patients with pyelitis; and pus in urine, coming certainly from the kidneys, is an indication for abortion.

Tonsil Exeisions.—DR. A. G. HOBBS, of Atlanta, read a paper on this subject, reporting over four thousand cases and presenting a new and improved instrument.

Extirpation of the Rectum for Carcinoma, was the title of a paper read by DR. MCFADDEN GASTON, of Atlanta. He reported a case in which the patient did well after the operation for eight days, when he died of septicæmia.

The Treatment of Hæmorrhoids by Carbolic Acid Injections.—DR. J. W. HALLUM, of Carrollton, read a paper on this subject. His mixture is pure carbolic acid one part, and pure glycerine two parts, and enough morphine and tannic acid that ten drops of mixture will contain one-quarter of a grain each.

Election of Officers.—*President*, Dr. A. A. Smith, of Hawkinsville; *First Vice-President*, Dr. George J. Grimes, of Columbus; *Second Vice-President*, Dr. R. H. Taylor, of Griffen; *Treasurer*, Dr. C. E. Goodrich, of Augusta; *Secretary*, Dr. D. H. Howell, of Atlanta.

The Association adjourned, to meet in Americus, on the third Wednesday in April, 1893.

Medical Heroism.—Three men were recently rendered unconscious by fumes while clearing out a blast furnace at Sunderland, England. Dr. Glen ascended to where the men were working on the top of the stove, lashed himself to a rope to prevent his falling, and for fully an hour applied artificial respiration, his efforts being finally crowned with success.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SIR WILLIAM ROBERTS ON THE CAUSES AND TREATMENT OF URIC ACID GRAVEL—CHIMNEY SWEEPS' CANCER, IS IT DECLINING?—THE LATE SIR WILLIAM AITKEN, F.R.S.—SIR WILLIAM ROBERTS ON THE CHEMISTRY AND THERAPEUTICS OF GOUT—MEDICAL CANDIDATES FOR PARLIAMENTARY HONORS—THE FULHAM SCARLET-FEVER CASE.

LONDON, July 2, 1892.

In my last letter I said that Sir William Roberts, in his recent lectures at the College of Physicians, stated that deficiency of salines and of coloring matter in the urine might be regarded as factors in the chemical etiology of uric acid gravel. Deficiency of saline matters, he said, was probably an influential factor in the disproportionate frequency of stone among the children of the poor, and its undue prevalence among the natives of India. The children of the poor were fed largely on farinaceous articles, and rice formed a large part of the diet of the natives of India; in both cases there was a deficiency of mineral matters in the food. On the other hand, the well-known immunity of sailors from stone and gravel depended, no doubt, as shown by Mr. Plowright, on the prodigious quantity of salt they habitually consumed with their food. In chronic Bright's disease, where, with contracting kidneys, the urine was conspicuously pale and often almost entirely devoid of pigment, deposits of uric acid were not uncommon, and actual renal gravel sometimes occurred; the percentage of salines was also low, but probably the most potent factor in the precipitation of uric acid in these cases was the deficiency of pigment in the urine. Poverty of the urine in salines and pigments, however, only accounted for certain limited groups of calculous cases. Calculous patients among the easy classes—especially those of a gouty type—usually voided a urine which was full colored and abundantly rich in salts, and we must seek in some other direction for the cause of the morbid tendency. The lecturer thought that in such cases the determining factors were to be found in the proportion of uric acid in the urine, and in the degree of acidity of the urine. A sharp distinction should be drawn between the percentage of uric acid in the urine and its rate of secretion. The proportion of uric acid in the urine bore no constant relation to the rate of its excretion by the kidneys. The discharge of uric acid reached its highest level during the digestion and absorption of food, but its percentage in the urine was not high, owing to the fuller volume of urine at this time. On the other hand, after prolonged fasting and during sleep, the hourly discharge of uric acid sank to its lowest point, but its percentage in the urine touched its highest pitch. The occurrence of uric acid gravel, moreover, was not a reliable proof of an excessive output of uric acid, nor even of an undue percentage of the same. It was, though, susceptible of proof that, other conditions being favorable, a high percentage of uric acid in the urine became a potent factor in the determination of uric acid precipitation, and Sir William Roberts quoted some observations which he had made on this point. Speaking next of the acidity of the urine, he said that, in some cases of gravel, he had found it twice as high as the normal average. In two such cases the urine was found to decompose the purified amorphous urate as rapidly as distilled water; when, however, its acidity was reduced to the normal level by the addition of sodium carbonate, it had then no more power in this respect than healthy urine, showing clearly that the determining factor in these cases was solely excess of acidity. Experimenting on normal acid urines, it was found that the addition of an exceedingly minute quantity of an alkaline carbonate postponed the time of precipitation of uric acid very notably. The differences between the alkaline carbonates of potassium, sodium, and lithium were only found to be such as were proportionate to the differences between their atomic weights.

From these considerations Sir William Roberts passed on to the treatment of uric acid gravel. He pointed out that this must be mainly preventive, and that the chemical force requisite to prevent the precipitation of uric acid in the urinary channels is almost infinitely small as compared with the force necessary to redissolve a concretion already formed. It was important to fix our eyes on the urine itself. Uric acid gravel was constantly seen as an independent disorder in persons otherwise healthy. The circumstance that uric acid figured as a common factor in both gravel and gout had led certain persons to the opinion that the two complaints were identical. This was not correct. Many gouty persons were never troubled with gravel, and many subjects of gravel were never troubled with gout. He was satisfied, from repeated observations, that in the immense majority of cases of uric acid gravel in this country the immediate determining cause of the precipitation was excessive acidity of the urine. The most important point in preventive treatment was to diminish this acidity, and all other schemes of treatment sank into insignificance beside this. The deposition of uric acid was most imminent when there was a conjunction of the several conditions, *i.e.*, when the urine was scanty, hyperacid, and rich in urates. Such a conjunction was most fully developed during sleep—during which period, also, the renal stream was most stagnant. A study of the facts indicated that if we safeguarded the night, the day might generally be left to take care of itself, and this theoretical consideration was fully in accord with experience in the treatment of uric acid gravel. In the milder cases a single full dose of the alkalizing agent taken at bedtime sufficed to prevent the recurrence of colicky pains and the discharge of uric acid concretions. The citrates and bicarbonates of potash and soda were the most effective. The citrate of potash was perhaps the best preparation, as it had little taste and sat comfortably on the stomach. The dose for an adult should not be less than from forty to sixty grains dissolved in three or four ounces of water. In severer cases, a second but smaller dose should be taken in the night—not a difficult matter to arrange with calculous patients, who rarely passed the night without a call to empty the bladder. In some cases additional doses of the antacid were required, and the right time for these was two or three hours after breakfast and two or three hours before dinner. A matter of some importance in the management of cases was the arrangement of meal times. Each meal acted on the urine as a dose of alkali, and also as a diluent, and in both these ways operated as a protective against uric acid precipitation. Subjects of gravel should be warned not to allow too long an interval to elapse between their meals. Referring to the contradictory advice on diet and regimen given by various writers, the lecturer said that the only point which had been really made out was that the excretion of uric acid was diminished by lessening the albuminoid ingredients of the food. But this class of aliments was absolutely essential to nutrition. It appeared that the only practical outcome was this: that persons subject to uric acid gravel, and who were also troubled with a large appetite, should seek to lessen their cravings and to lessen the intake of nitrogenous material by the free use of farinaceous articles of food; with salads, fruit, and garden vegetables, all of which were comparatively poor in albuminoid constituents.

It has long been an accepted surgical doctrine that chimney-sweeps' cancer is becoming less common in this country. Dr. William Ogle called this view in question a few years ago, and in lecturing on the subject recently at the College of Surgeons, Mr. Butlin, retracting his own former opinions, produced evidence which may be said to completely pulverize the doctrine in question.

He showed that it has always been a rare affection, but pointed out that it was not becoming rarer. It was undoubtedly rare in other countries—a circumstance which Mr. Butlin attributed to the superior protection afforded by clothing and washing, as to which he gave some interesting information which he had obtained. He agreed that chimney-sweeps' cancer is a comparatively mild malignant disease. Quoting statistics as to the incidence of malignant disease in various parts of the body, he said it might safely be averred that the tissues of the scrotum were not in the least disposed to the occurrence of cancer. The inference was strong that there was something in the trade of a sweep which modified the skin of the scrotum to such an extent as to render it liable to the occurrence of cancer, more liable than the integument of any other part of the body; for sweeps were not more liable than other persons to cancer of the face, lips, and other parts. Everything led to the belief that the effect of the soot was merely to prepare the tissues of the scrotum for the occurrence of cancer, either by its mechanical or chemical influence, and the evidence was strongly in favor of the latter, for there was immunity from cancer in other callings which exposed the scrotum to mechanical irritation. There were cases on record showing such an influence from the application of soot to other parts of the body.

British medicine sustains a loss by the death of Sir William Aitken, Professor of Pathology at the Army Medical School, Netley, which took place this day week. Army surgeons will remember Aitken as a pathologist and as a teacher, and his pupils must be many, for it is thirty-two years since he received his appointment. His large "Manual of Medicine" made him known to a larger circle, and for years it was regarded as *the* book to read for the higher examinations. His death will cause general regret, for he was highly esteemed.

London, July 9, 1892.

In his third "Croonian Lecture," Sir William Roberts traced the chemical history of uric acid in relation to gout. He said the evidence brought forward by Sir Alfred Garrod appeared to him to be conclusive in favor of the view that the deposition of the crystalline biurates was the actual cause of the joint troubles in gout. The lecturer described a number of experiments which he had made on the solubility of sodium biurate in various media. In distilled water it dissolved pretty freely (1 in 1,000), but in blood-serum or synovia but sparingly (1 in 10,000). He found that a solution in water of the salines of blood-serum behaved with uric acid and the waters exactly like serum itself, and this fact was made use of in investigating the chemistry of the urates, though the results obtained were checked by comparing them with those obtained with blood-serum in similar circumstances. With regard to the solubility of sodium biurate in saline solutions at the temperature of the body, it was found that the solubility was decreased by the presence of salts of lime, magnesia, or ammonia, and still more so by soda salts. Salts of potash had no effect either way. The influence of a salt was found to depend solely on the nature of the base, and alkaline salts did not differ in the least from salts with a neutral reaction. When uric acid was digested at the temperature of the body with blood serum it passed into solution in combination with a base. The combination could not be biurate, because sodium biurate was almost insoluble in blood-serum; nor could it be neutral urate, because the neutral urates could not arise in the presence of carbonates. The presumption remained that the combination was a quadriurate, and it was found to be so. The process, however, did not stop here, but the quadriurate gradually took up an additional atom of base and was thereby converted into biurate, and the biurate thus formed was, after some delay, eventually precipitated in the crystalline form. When synovia, instead of serum, was employed, precipitation of biurate began distinctly a little earlier. An interesting point in connection with the chemistry of the urates was the occurrence of gelatinous modifications of them: Dr. Ord had regarded these forms as true colloids, but Sir William Roberts thought they were hydrated salts. It might be inferred from the facts put forward that in the normal state uric acid was primarily taken up in the system as a quadriurate, that it circulated in the blood as a quadriurate, and that it was finally voided with the urine as a quadriurate. In perfect health, elimination was sufficiently rapid and complete to prevent any undue accumulation in the blood. In the gouty state this tranquil process was interrupted, either from deficient action of the kidneys, or from excessive introduction of urates into the circulation, or from some other cause, and the quadriurate lingered unduly in the blood and accumulated therein. Circulating in a medium rich in sodium carbonate, the quadriurate gradually took up an additional atom of base, and was thereby transformed into biurate. This altered the physiological problem. The uric acid—or, rather, a portion of it—no longer circulated as the more soluble and presumably easily secreted quadriurate, but as the less soluble biurate, which was probably less easy of removal by the kidneys. The biurate thus produced existed at first in the gelatinous modification, but with the lapse of time and increasing accumulation it passed on into the almost insoluble crystalline condition, and then precipitation became imminent, or actually occurred. It was experimentally found that these changes took place more rapidly at 100° F. than at the temperature of the room, and also increased in rapidity as the proportion of uric acid in solution increased. The addition of sodium salts hastened precipitation; that of potassium salts sensibly retarded it, but did not appreciably diminish its eventual amount. Calcium and magnesium salts delayed precipitation, but their action in this respect was insignificant, or even doubtful.

In his fourth lecture Sir William Roberts discussed the topography of uratic deposits. Analyses showed, he said, that the tissues which were most liable to uratic deposits were those which were richest in sodium salts; this corresponded with the fact shown in the laboratory, that the dominant factors in uratic precipitations were the proportion of urates and of sodium salts in the solvent medium. The connection between synovia and gouty deposits was evidently very close and special; synovial fluid had itself been repeatedly found heavily laden with crystals of sodium biurate. With regard to the articular cartilages it could be demonstrated that the uratic precipitation actually took place from the synovial fluid, and was not self-originating in the cartilaginous substance. This process could be artificially imitated in the laboratory, and a counterfeit gouty joint could be produced in the articulations of a dead animal. Why did gouty precipitation take place preferentially in synovia rather than its cognates, the serum of blood and lymph? Why did the joints differ so much from each other in their liability to attack? It might be that there was some special attraction in the joints for uric acid. Synovia, also, was a comparatively motionless fluid, while serum and lymph were in ceaseless motion. Then, as regarded the varying liability of different joints, it was an observed fact that the synovial fluid in different joints presented differences in the relative proportion of their constituents. Frerichs had shown that in animals the synovia varied with the mode of life. In idle animals the synovia was more watery, but contained a larger proportion of mineral salts, which might consist almost entirely of sodium salts. We might, perhaps, here discern a reason why sedentary patients were more subject to gouty deposits.

With regard to the mode in which uric acid acted injuriously on gouty patients, Sir William Roberts thought the mechanical theory offered a natural and complete explanation. The crystalline urates precipitated in the joints acted as foreign bodies and excited irritation. This theory had been regarded as inadequate to explain the phenomena of irregular gout, and it had, therefore, been assumed that uric acid was possessed of toxic properties.

He could not, however, accept the latter view, and he thought that uratic precipitation in various parts of the body afforded a sufficient explanation of the phenomena of irregular gout. This mode of viewing the subject enabled us to bring the diverse morbid effects of uric acid into uniform line. Uric acid and its compounds were deleterious simply because of their sparing solubility in the bodily media. It might be said that the final cause of uric acid gravel was the sparing solubility of free uric acid in urine, and that the final cause of gouty precipitation was the sparing solubility of sodium biurate in blood-serum, lymph, and synovia.

Coming next to the subject of treatment in gout, the lecturer remarked that it had been shown that one of the main factors in determining uratic precipitation was the percentages of urates in the medium. The ingestion of large quantities of proteid matter was attended with an increased production of uric acid. It was not clear that animal proteids differed in this respect from vegetable proteids. But as the commonly used articles of food of animal origin were richer in proteids than the commonly used articles of vegetable origin, it was true that a vegetable diet was less productive of uric acid than an animal diet. The most trustworthy experiments indicated that fat, starch, and sugar had no direct influence on the production of uric acid, but as the free consumption of these articles naturally operated to restrict the intake of nitrogenous food, their use had indirectly the effect of diminishing the average production of uric acid. He had been in the habit for some years of directing gouty patients to restrict their consumption of common salts. Lessening the intake of salt with food only abated its proportion in the blood to a slight extent, because the blood had the faculty of extracting salt from the fluids and tissues of the body; but, this being so, the amount of salt in the synovial fluids and fibrous tissues was considerably diminished by such a regimen. Medicinally, alkalies had been largely used in the treatment of gout, but modern researches went to show that the belief in an acid dyscrasia in gout rested on a pure assumption. Carbonate of lithia and piperazine had been, on chemical grounds, introduced into the treatment of gout, but he had found experimentally that the addition of minute amounts of these substances to blood-serum or synovia had no effect in enhancing the solvent power of these media on sodium biurate, nor the slightest effect in retarding its precipitation from serum and synovia artificially impregnated with uric acid. If these bodies had any beneficial action in gout, it was certainly not due to their solvent action on the material of gouty concretions. As to the use of mineral springs, those containing sodium salts should be avoided, or used but sparingly. There could be no doubt that the efficacy of "indifferent" waters depended on their watery constituent. They diluted the blood temporarily, and lowered its percentage of urates and sodium salts.

The medical candidates for parliamentary honors have not been very successful at the polls as yet. Dr. B. W. Richardson, F.R.S., has been defeated, as also has Dr. Verdon, Medical Officer of Health for Lambeth.

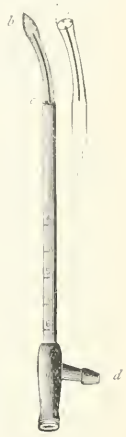
Scarlet fever is considerably on the increase in London. A recent case, at Fulham, has excited considerable discussion, and is likely to be quoted frequently in the legal interpretation of the Act for the compulsory notification of infectious diseases. A conflict of opinion took place as to the nature of the disease. The medical officer of health pronounced it to be scarlet fever, and so did several other medical men. The mother, though, had sought other advice, and the medical man she had summoned obtained the opinion of Dr. Phillips, Physician to the London Fever Hospital, and of Dr. Cayley, Physician to the Middlesex Hospital and Consulting Physician to the Fever Hospital, that the case was not of such a nature. A magisterial order had been issued for the removal of the child to one of the fever hospitals, but this was disregarded and Dr. Cayley took the child into the Middlesex Hospital. The magistrate censured Dr. Cayley and inflicted a fine of ten pounds on the mother, which, however, has been remitted by the Home Secretary.

New Instruments.

AN IMPROVED CATHETER, AND SOME REMARKS ABOUT TREATING THE URETHRA.

By C. WAECHTER, M.D.,
NEW YORK.

CHRONIC inflammation of the urethra depends most generally—aside from strictures—upon diseased conditions of the posterior portion of the canal, especially the pars prostatica; anteriorly it is usually but little affected, and for this reason, in treating it, it is useless to make injections by means of a common syringe, since they will not reach the seat of lesion. Consequently the treatment of chronic gonorrhœa is attended frequently with considerable difficulty, the more so if strong remedies be used, producing great pain in the anterior part of the urethra.



For some time past it has been my desire to find some simple means by which the posterior part alone of the canal could be treated The present instruments (*i.e*, Ultzmann's tube, the endoscope, etc.) answer but partly all indications. After many unsuccessful attempts I have now been able to have an instrument made which answers the purpose admirably. The accompanying figure demonstrates itself. The injecting fluid enters at *a*, running through a narrow canal, and making its issue at the point *c*, whose openings are directed backward. The fluid comes then in contact with the mucous membrane, re-enters the catheter at *c*, and flows off at *d*. Consequently the anterior part of the canal is entirely avoided, and strong solutions of nitrate of silver, etc., can locally be applied without producing any considerable pain.

The course of my procedure is therefore as follows: A patient presenting himself with a chronic inflammation of the urethra is thoroughly examined by means of the bulb sound or endoscope, and the condition of the urine is also ascertained. Is it, for instance, a case of chronic gonorrhœa seated in the prostatic portion, I irrigate the entire canal with some weak antiseptic solution—boracic acid, or, as has been of late recommended by Professor Winternitz,[1] a decoction of whortleberries. Is the irritation in consequence of the first examination but little, the irrigation is continued the next day, and a bougie is applied as far as the neck of the bladder. A weak solution of argent. nitr. (one sixteenth grain to the ounce) is then used and brought in contact with the entire canal in order to diminish the sensibility of the mucous membrane and neck of the bladder. At each successive treatment the strength of the solution is increased, sounds are used, besides lukewarm sitz baths, a proper diet, and internally, alkalies, etc. In the meantime the patient is ordered to use a deep injection of a weak astringent once or twice a day. If a catarrh of the bladder be present, irrigations of boracic acid, alum, or nitrate of silver are employed. After the irritability of the mucous membrane in this manner is arrested, I make use of a stronger solution of silver, with the above described catheter, every second or third day, up to a strength of fifteen or twenty grains to the ounce. The injections are borne, as a rule, without any inconveniences. I have in this way been enabled to cure obstinate cases, although they may have existed for years.

[1] Blätter für klinische Hydrotherapie. Wien.

It is quite prudent to cleanse the urethra with tepid water when the catheter is introduced before making the injections. In order to bring the solution in contact with the entire mucous membrane, the catheter should be slowly turned while injecting.

This catheter has been especially beneficial in cases of spermatorrhœa; the solution finally used of nitrate of silver is forty to sixty grains to the ounce, without producing great pain to the patients. I may here mention the fact that spermatorrhœa is more frequent than is generally acknowledged. If the urine of a patient suffering from chronic prostatitis (sexual weakness, neurasthenia) be examined as the same is voided during defecation, frequently spermatozoa are detected. Even a small unnatural loss of semen may cause a considerable disturbance to the nervous system. I am now about investigating whether a similarly constructed instrument can be made for the use of the uterus or rectum.

The catheter is made of hard rubber, as is also the syringe; the former can be separated into three parts, easily cleansed, and is manufactured in different sizes.

220 East Tenth Street.

AN IMPROVED STETHOSCOPE FOR USE IN AUSCULTATORY PERCUSSION.

By F. W. KOEHLER, M.D.,
LOUISVILLE, KY.

While practising auscultatory percussion in the usual manner not long ago, the idea struck me that it would be an advantage to have a percussing apparatus inside the cylinder of a stethoscope. The dentists have an instrument, used for plugging teeth, the principle of which can, quite readily, be utilized in constructing such a percussion stethoscope. It consists of a cylinder which contains a metal rod, and has attached to one end a rubber bulb by means of a section of tubing. On compressing the bulb the metal rod is driven down, and on relaxing it it is drawn up.

The force of the blow given by the rod is of course dependent on the force exerted in compressing the bulb, and is therefore under nice control. In adapting this mechanism to the stethoscope only one additional part is necessary, viz., a plessimeter.

This is attached to the margins of the bell of the stethoscope in such a manner that its surface projects slightly. It is, however, so attached that when the stethoscope is pressed upon the body of the subject to be examined it is forced back, thus allowing the margins of the bell to come in contact with the flesh. The plessimeter remains, no matter what the position of the subject may be, in close apposition to the body. On compressing the bulb of the instrument the metal, or, better, hard-rubber, rod is driven down on the plessimeter and the characteristic sound of the part percussed is conveyed with great clearness to the examiner's ears.

Tafel Brothers, of this city, are getting the instrument out for me. It will be so arranged that it may be attached to the upper part of any ordinary binaural stethoscope.

It seems strange that such an instrument should not have been already invented, but as far as I know it has not been. I do not remember to have seen any notice of the contrivance in any text-book with which I am familiar, nor have I found it in any surgical-instrument catalogue.

Pemphigus Neuroticus.—Dr. Neuberger speaks of a case similar to that described by Doutrelepont, under the name of multiple gangrene of the skin, and which Kaposi has designated zoster gangrenosus atypicus hystericus. The patient was a female, aged twenty-six, and very hysterical. She rapidly sank, and after death syringomyelia. Contrary to the case reported by Kaposi, necrosis of the epithelium first took place, and that of the papillary layer followed.—*Journal des Maladies Cutanées*, May, 1892.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 30, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	34	17
Scarlet fever	48	8
Cerebro-spinal meningitis	0	2
Measles	149	22
Diphtheria	72	27
Small-pox	7	1
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

An Action for Libel against an Egyptian Paper.—Dr. Milton, of the Native Hospital at Cairo, has brought an action for libel against *Le Bosphore*, a newspaper of that city, on account of a violent article attacking the English doctors practising in Egypt, and containing allegations regarding them which are declared to be wholly without foundation. Dr. Milton claims substantial damages.

The Physician and Literature.—It is sad to hear it commonly said that the day of learned physicians is past, that they are gone with periwigs and bric-à-brac. And I have had already to observe to my pain that the Cambridge medical student of to-day is by no means "learned;" that too often he thinks loosely, and that he does not always write even the English of the gentlemen who do the fires and the murders for country journals. On his Latinity I will discreetly keep silence. Hence I fear that we are not only changing our methods, but losing sight of our standards, and of this we have said we are to beware; we may well desire, nevertheless, to see not only change but even a revolution of the methods of teaching in public schools as well as in our own classrooms—methods now hopelessly astray. Yet one of my colleagues in the last medical and surgical examinations said to me: "A physician should be a kind of poet"—a hard saying, but a saying of deep wisdom. For to their patients what are the most scientific physicians, if they be διανοητικοὶ πνεῦμα μὴ ἔχοντες, if they know all things save the human heart? "On ne connaît jamais parfaitement que celui que l'on devine." How in Cambridge are we to endow young men with these riches of experience and to give them this faculty of divination, save by literature? We will repeat that a method is an economy; a true method is a path leading us directly into the centre of the experience of the world, leading us, early in life and with ease and pleasure, whither millions of weary travellers have never come, giving us what millions of hearts have yearned after but yearned in vain. Our disciples must come to us not only for mental furniture, not only to learn a gainful craft, but to breathe here the spirit of disinterested knowledge and of wide humanity.—Professor Clifford Allbutt, Inaugural Address.

Purèe de Bacilles à la Chicago.—The American Health Resort Association, an organization for the collection and dissemination of reliable data as to climate, health resorts, and mineral waters, for the guidance of the medical profession, met at the Tremont House June 30th. Professor W. S. Haines, of Chicago, read a paper, in which he said: "Water that contained up to two hundred and fifty bacteria to the cubic centimetre was classed as good water." In Chicago water examined by him during the last few months he found at no time less than two thousand bacteria to the cubic centimetre, and sometimes as high as eight thousand.—*Chicago Tribune.*

PAPERS ON DISEASES AMONG INDIANS.

BY A. B. HOLDER, M.D.,

MEMPHIS, TENN.,

ASSISTANT PROFESSOR OF PHYSIOLOGY MEMPHIS MEDICAL COLLEGE, ETC.; FORMERLY AGENCY PHYSICIAN, CROW RESERVATION, MONTANA.

(Illustrated by photographs taken by the author.)

SANITARY EFFECTS OF CIVILIZATION.

THE impression that civilization is fatal to the Indian constitution—that, like the hare or the quail, under efforts at taming he will pine and die—is a part truth that leads to much error. The "transition period," so indefinite and so much dreaded, has danger only under mismanagement. I will state my opinion of the matter thus: *If the Indian were lifted at once from the wildest savagery in which he can now be found, to full civilization—that is, to comfortable and hygienically constructed clothing and housing, to abundant and well-prepared food, to a knowledge and practice of the rules of health governing the more intelligent individuals of the white race—his condition would at once and permanently be greatly improved as to health and longevity.* On the other hand, *his primitive savage state was better as to health and longevity* (*and in parenthesis I may add morals as well*), *than the partly civilized state in which he now exists.*

The evils of imperfect civilization and misapplied efforts at civilization, however, are serious enough to deserve careful attention.

Agent James McLaughlin, for years in the Indian service, describes these conditions in the following words ("Comr. Report, 1887"):

"There is no doubt that the Dakotas of the 'Great Sioux Reservation' are decreasing, and that the decrease has been gradual for several years past, as was shown by the falling off in numbers at the various agencies when all were enumerated on the same day, September 30th last. A slight diminution is likely to continue through the present transition period, while passing from the wild nomadic life to civilization, and until they have learned to obey the more important laws of health. The indifference of the Indian to exposure, disregard for wet feet, irregular habits, eating at one meal sufficient for several, frequently eating a dozen times a day, and again going without food for a great length of time, together with the exhalations from their floorless and poorly ventilated cabins, cannot but be detrimental to health and tend to the development of fatal diseases."

As in morals they have received the evils of civilization, so in sanitation they have received its evils—bad ventilation, over-heated houses, etc.—and have not yet attained to its advantages.

Even more minute and accurate is the description of Dr. Nat. McKitterick, of a branch of the same nation (Sioux):

"The transition of these Indians from their savage state has made changes in their physical condition. Their mode of cooking and living by chase was conducive to health and the development of the muscular system. Living in the tepee or lodge had the same effect, for the laws of sanitation were easily lived up to; when the surroundings became uncomfortably dirty, the tepee was moved to some clean spot. But since the advent of the log-house among them, things have changed; it is not practicable to move the house, and not being the most thrifty and industrious people in the world, the filth remains about the house. Their food being different from that to which they were formerly accustomed, they have never learned to cook properly; their crude way of cooking and making bread does not stimulate digestion, hence cathartic remedies are an essential feature in their lives."

On this reservation,[1] to replace the cloth tepee, have been built a number of log or frame cabins; the latter are 16 × 18 feet, rooms 8 feet high, with double dirt-filled walls, dirt roof, one door, and in the case of fifty built three years ago, one window in a single fixed sash. Fifty built more recently have the single window of two small, movable sashes. In this one room are placed usually two stoves, one for cooking, and one for heating. Often in winter, with all openings closed, fires are kept burning in both stoves, and inhabitants to the number of ten or more occupy the room.

Let me appeal to physicians, to those in authority, and to the public, that there be less talk about "problems" and "policies," and more attention to housing, sanitation, and morals of our Indian wards.

The most powerful facts toward proving the sanitary benefit of civilized surroundings are to be seen in the case of children brought from the camp to the boarding-schools, where they are at once placed in correct hygienic conditions.

The benefit of this change, where the child is not carried to a different and less salubrious climate, is observed in every case; the benefit is rapid, decided, and permanent, in the opinion of all physicians who are so situated as to observe its effects. It is emphasized by the return of the child already improved in health from the school to the camp; many children are then seized with pneumonia or consumption, and quickly carried off.

In this connection I desire to call attention to the evil of too long confinement of Indian children at study or recitation. It is the custom at many schools to so occupy them for seven or eight hours. This is excessive for a child during his first few years of school life, or indeed ever. I should say four, or at most five, hours, including the one hour in the evening required by the Indian office regulations, should be the extreme limit.

The impression prevails among agency physicians that the transfer of Indian pupils from their reservation to schools of different altitude and latitude is often harmful. From Crow Creek, Dak., comes the statement (Dr. Treon): "Decidedly improved by transfer to school, but cannot stand any radical change in climate; the mortality among the children sent from here to Hampton has been very heavy." From Anadarko, I. T., Dr. W. W. Graves: "The change from camp life to that of the boarding-school is anything but favorable to health, so far as relates to Carlisle and other schools in cold northern sections. It is very different when they attend the school we have here, where the children are in the same atmosphere where they have been born and reared."

That Indians suffer severely from change of climate has been shown many times. Its destructive influence was especially felt by the Poncas, and by Joseph's band of Nez Percés, transferred, the one from Dakota, the other from Idaho, to the Indian Territory, and of the Cheyenne and Arapahoe Indians from the Northwest to

[1] "This tribe," or "this reservation," when used in these papers, refers to the *Crow* tribe or reservation, where the author was stationed.

the same section. All these a few years later, having become accustomed to the climate, suffered less.

I have endeavored to accumulate statistics bearing on this point, but they are not so full nor so accurate as to enable me to make a safe deduction.

Captain Pratt, in a private letter, kindly furnishes me the following figures, for the ten years 1879 to 1889 :

Aggregate attendance	4,021
Number returned to reservation on account of ill health	162
Number of deaths during school year	98
Or the averages for year attendance	402 1/10
Sent home for ill health	16 2/10
Died	9 8/10

These statistics are valuable, but as I have not equally accurate from reservations or reservation schools, I am unable to make a comparison.

Dr. Martha M. Waldron reports for Hampton during ten years :

Attendance	467
Died	31
Sent home for health	111

I am myself of the opinion, however, that the mortality is greater in Eastern schools, than at schools on reservations, and less than in the camp. This statement is entirely without prejudice, since I strongly favor Eastern schools for the education of Indian children.

Tuberculosis among Indians.

Consumption and scrofula are the arch-enemies of Indian life ; unlimited by tribe, latitude, or longitude, by altitude or humidity ; just as they are known to all nations and all countries, so they find their victims in every tribe and stand between the Indian race and increase.

Of 1,453 deaths from all diseases in 1888, more than 900 were from diseases of the respiratory organs and scrofula. From consumption alone there were 541 deaths ; that is, nearly forty per cent. of all mortality was due to the single disease, consumption. This percentage, I think, was rather less than for other years (whose statistics are not at hand), since the winter of 1887–88 was exceptionally mild and favorable to consumptives.

A recent author [1] who has made a special study of this disease, develops the figures that of the thirty-five million deaths occurring annually upon the globe seven million are due to phthisis. This is twenty per cent. So, at the very safe rate of deaths from consumption among Indians given above, it is seen that the proportion caused by this disease is double the average for all races. In many tribes the proportion goes much beyond this, some physicians reporting fifty to seventy-five per cent. of deaths from this cause. Of 57 deaths among the Indians of Crow Creek Agency, Dak., 40 were from consumption, 4 from scrofula. Dr. Fred. Treon, the physician, in a paper before the Dearborn County (Ind.) Medical Society, says the yearly average is 40 deaths from consumption in that tribe of 1,200 Indians. Its importance cannot be over-estimated.

Probably in his primitive state of savagery, certainly in his present state of transition, the stamina of the Indian constitution is inferior to that of the white man. From due consideration of the matter my conclusions are : *The physical changes consequent to civilization increase in equal proportion proneness to disease and resistance to disease.* Concretely stated, the savage is less liable to become sick or be injured, but when sick or injured to the same degree, is more liable to die than a civilized man.

In an essay, Emerson uses this illustration, "Compare the health of the two men"—the savage and the civilized —"and you see that his aboriginal strength the white man has lost. If the traveller tells us truly, strike the savage with a broad axe, and in a day or two the flesh shall unite and heal as if you struck the blow into soft pitch, and the same blow shall send the white man to his grave." It has been a popular impression that in the degree in which the savage fell below perfection in mental endowment and development, in that degree he possessed physical robustness. This is but partly true. Savage races are healthy races just in the proportion that their lives are in accordance with the fundamental laws of health. Free from many disease-breeding causes found in civilization, they may escape these diseases ; if, on the other hand, their condition leads to exposures and other hygienic abuses avoided by civilized races, they at once meet the penalty.

Indians never attained that purity and simplicity of living which defies disease. When the Pilgrims landed in 1620, Somoset, a Wampanoang Indian, told them a "great plague" had destroyed most of the Indians who lived near about. I do not believe that at any time in their history they have been free from consumption and scrofula.[1] The many reasons for its vast increase in recent years will be advanced presently. I do not think the proneness to pulmonary troubles is new, nor due to civilization, nor a result of venereal inoculation.

That their resistance to disease is much less than that of the civilized races, I have seen the evidence at the bedside, in watching them yield and die from diseases that I felt sure any stout white man had easily thrown off. This is especially true of pulmonary diseases. I have never seen a plain case of catarrhal pneumonia (the usual form) make a perfect recovery, or, indeed, escape death eventually from phthisis.

Dr. O. S. Given, for many years physician-in-charge of various Indian tribes, states his conclusion thus : "The uncivilized man has not a good physical constitution. Indifference to exposure, utter disregard of all sanitary laws, irregular habits, alternating of gormandizing and fasting, consanguineous marriages, all tend to physical deterioration."

Captain Pratt, Superintendent of the Carlisle (Pa.) Indian School since its organization, asserts that mixed bloods even resist disease and death from pulmonary troubles better than pure bloods.

William G. Coe, Agency Physician to the Klamath Agency, Washington Territory, in his report for 1887, says : "Their powers for resisting disease are inferior to those of any race of which I have knowledge, and this is due not only to the fact that they are adynamic from hereditary disease characterized by struma, but all their habits tend to debilitate and render their recuperative powers nil."

The resistance to disease of the negro race is well known to be less than that of the whites. From a considerable experience in the treatment of both races I am fully convinced that the resistance of the Indian is less than the resistance of the negro. This is observed notably in the Hampton (Va.) Industrial School, where Indians and negroes are educated side by side. ("Comr. Report for 1887," p. 264.)

Tuberculosis is co-extensive with the Indian race. The single tribe that may be said to be free from these diseases I have been unable to find after diligent search. Those who inhabit the torrid sands of Arizona, and those in the frozen Northwest Territory of Canada, along the Western seaboard and in the Atlantic States—all tribes suffer more or less from consumption and scrofula. Certain tribes living in the arid regions of the Southwest, and others on the Pacific coast, I believe, are freest.

In the Indian Territory, and among a few tribes elsewhere, malaria becomes of greater importance than consumption as a mortality cause.

A popular impression that a malarial climate is a favorable one for consumptives, finds no confirmation in the history of Indian tribes, save that tribes whose chief cause of death in the Northwest was consumption, have died

[1] George A. Evans, M.D. : Handbook of Historical and Geographical Phthisiology, etc.

[1] In Peabody Museum (Specimen, 17,223) is a part of a vertebral column badly affected with caries—tuberculous—among prehistoric Indian remains. See cut, Orthopedic Surgery, Bradford & Lovett, p. 2.

with such rapidity from malaria when removed to a region where it prevails, that consumption becomes at once of minor importance.

Whether it be conceded or not that the savage was originally of inferior constitutional stamina, it is certain the "transition" has left him so. This has been written of elsewhere in accounting for the slowness of increase in Indian tribes. The sanitary evils in which they live are just those calculated to intensify a proneness to tubercular troubles, and to serve as exciting causes where the proneness exists. These evils may be classed as those of *dress, dwelling, and diet.*

The time is not beyond the memory of men yet living when many tribes of Indians lived in that animal simplicity that did not require any covering for the body save as protection from winter's cold. Then came the time of the fig-leaf, which period in their history is not yet past.

The usual *dress* of those tribes who have not adopted the habiliments of civilization is, for the male, a tunic or shirt; a breech-cloth, being a strip twelve to fourteen inches wide and two to three yards long, passed under a belt in front and behind, the ends forming front and rear aprons, the middle portions covering the parts about the breech; leggins and moccasins. Of these articles the only one essential to modesty and constantly worn is the breech-clout.

lodge or tepee, a conical tent of dressed buffalo robes having a single door at the side and a spacious opening at the top for the escape of smoke, and, incidentally, for ventilation. The fire was built on the ground in the centre of the lodge—the ascending current of warm air escaped at the top, and fresh air entering below and through the walls secured excellent ventilation. When the surroundings became at all unsanitary, the tepee was at once and readily moved.

The policy of the Government has been to confine them to special locations, and to induce them to occupy houses. This policy would be good were proper houses provided. Forty houses built for Indians of this (the Crow) reservation by Government contract, are each a single room 16 × 18 × 8 feet, with double, dirt-filled walls, dirt roof, one door, and one window of a single fixed sash. The condition within in winter is well described by Dr. W. McKay Douglass, of the Santee Agency, Neb. (1887): "Visits to their domicile at this time of the year impress me deeply. Mercury is below zero, wind blowing a gale, snow drifting high when I knock at the door for admission. In a tight little Government house I find all the cats, dogs, babies, and other members of several families congregated and unengaged, save in smoking, talking, and sleeping. Dogs fare equally with the human occupants. The windows are closed, and

Indian Lodge, and Method of Jerking Meat.[1]

The female dress is a single skirt fastened at the waist, or more commonly a loose gown reaching the ankles, with large sleeves, and bound by a belt at the waist; close-fitting leggins and moccasins.

In winter some addition is made of robes or blankets, which serve as clothing in day and bedding at night.

This style of dressing, from its construction and from the inferior quality of material substituted for the former rich robes, is not sufficient protection against severe weather.

The moccasin is especially objectionable, since it is soon soaked when the ground is wet and becomes worse than no covering at the time when foot-covering is most needed. Stout but soft shoes should by all means be issued to Indians by the Government; the brogans now furnished them are unbearable to the foot accustomed to the moccasin.

The Indians' unappreciation of exposure may be illustrated by this, that I have had them ride several miles in the rain, or walking, wade the ice-cold river, to get medicine for a cough.

The primitive *dwelling* of all plains Indians was the

these people and animals are breathing an atmosphere which has been polluted by the exhalations from disintegrating lung-tissue and the emanations from open sores."

I find such houses often occupied by fifteen or twenty persons, and heated by two stoves, the smoke exit being a tight flue; open fireplaces, of such value in ventilation of small houses, being unknown.

In winter Indians plunge from these furnaces into the below-zero outside air, thinly clad, fully realizing the evil result that might be anticipated. Differing from this in degree only is the evil result of the sweat-house, which will be minutely described elsewhere. Its influence on the production of pulmonary diseases is only equalled by its influence in bringing them rapidly to a fatal conclusion.

Houses occupied by other tribes differ in construction, but are alike in danger to health. The dwellings of the Pimas and Maricopas of Arizona, until the recent building of adobe houses, were half-spherical-shaped mounds, twenty feet in circumference and six feet high at centre, with single opening at the ground, constructed of branches of trees and straw woven with much ingenuity and covered with dirt. Some tribes of Apaches make their houses by excavating the sand a few feet in depth and covering over with poles, brush, and earth. In such

[1] The meat is cut in thin slices and hung in the sun or over the fire to dry, and this, called "jerked" buffalo or beef, may be kept indefinitely.

houses live often from ten to thirty persons. The Pueblo house is built of sand, stone, and mortar, from two to four stories high, and is entered through a small aperture by means of a ladder, which aperture is the only source of ventilation except that some larger dwellings have windows and doors. As the buffalo furnished robes for dress and skins for dwellings, so his meat was in former days the staple, almost the sole article of *diet* of the plains Indians. Abundance of wild meat "jerked" or dried, without salt, with a scanty supply of roots and wild berries, was the Indians' primitive diet.

The buffalo is gone, and Government rations, or scant subsistence obtained by their own labor, is the Indians' present diet. In this change is found a factor in the causation of consumption and scrofula.

Rations furnished by the Government to Indian tribes are in most cases entirely insufficient to maintain health. These rations are issued once in one, two, or four weeks; usually in the first half or two-thirds of these periods all the rations are consumed. The next supply is received after two to five days of fasting, and is the material for a feast. This regular succession of fasts and feasts deranges digestion and assimilation, and fits the constitution for the invasion of tuberculosis.

Some facts bearing on the special effect of *certain articles of diet* on the production of one or both of these diseases may be noted. The charge that the meat of the hog produces a tendency to scrofula, is met by the fact that the use of this meat is almost unknown among Indians, who, of all people, suffer most from scrofula. It is also well known that Jews, to whom hog meat is prohibited, suffer much from this disease.

A report from the Carlisle school, bearing on the effect of the pork diet, is interesting (Red-Man, February, 1889). "Hundreds of students of Carlisle go out into farmers' families and remain months. They, almost without exception, return to the school improved in health. Taking seventy-five of these young men from the most scrofula-tainted tribes, such as the Sioux, Apaches, Cheyennes, Arapahoes, Crows, Pawnees, etc., who have thus been out of school one or more years, they were asked, one by one, what kind of meat they had most during their farm experience. Forty-nine said more than half of their meat was pork; thirteen others said less than half their meat was pork, and the remaining thirteen had beef and fish. Eating mostly pork and improving in health is some disproof of the theory of pork favoring scrofula." From Hampton, on the contrary, comes this report: "About a year and a half ago it was decided to restrict the Indians altogether from the use of pork, which they had before, like the colored students, in alternation with beef. This change has been evidently beneficial in its effect upon general health, especially upon scrofulous tendencies." It may be observed, while considering the matter of diet, that while the Indian was formerly almost exclusively carnivorous, and is very much so still, yet *scurvy* is unknown among them. Their meat was eaten unsalted.

Henry C. Chapman's "Physiology" asserts that "a deficiency of oil on the one hand, and of fresh vegetables on the other, produce phthisis and scurvy, respectively," which statement meets a singularly accurate opposition in the fact that Indians ate largely of meats and almost not at all of fresh vegetables, and are free from scurvy but ravaged by phthisis. The rareness of scrofulous scars in the older members of this tribe, compared with the immense frequency of the disease in the younger members, leads me to believe that it has greatly increased in recent years.

Pulmonary tuberculosis and scrofula have been included in the same chapters and discussed together. The reason for this is that they are practically inseparable. It is not my purpose to enter the controversy as to their identity or non-identity, or of their relationship in the latter event. I shall make simply a statement of the facts as I find them among Indian tribes, and my own conclusion from these facts that one of three states obtains: 1st, They are identical; or 2d, one is the cause of the other; or 3d, both are due to the same general causes. I should be willing to rest this conclusion on the single fact that they are constantly associated. If a considerable number of cases of one of these diseases exist in a tribe, then cases of the other will certainly be found in the same tribe. Pott's disease and other bone and joint manifestations of tuberculosis are common in all tribes.

I have avoided any reference to syphilis in connection with these diseases, in order to introduce here, in more conclusive form, some facts bearing on their relation.

The theory that *scrofula* is only a manifestation, in the second or third generation, of the *syphilitic poison*,[1] bears the impress of a name so great in American surgery that writers may be awed from attempt at refutation. If the theory be true, in every case there must have existed syphilis in the parents before scrofula may be found in the children; the greater the prevalence of syphilis in the parents, the greater the prevalence of scrofula in the children, freedom from syphilis in the parents giving immunity from scrofula to the children.

The following parallel columns exhibit, among some dozen tribes, the conditions as to the prevalence of these diseases. These are from reports to me of Agency physicians in 1889, and include all the reports wherein the conditions as to these diseases were clearly stated, except those—a majority—where all three diseases prevailed.

Prevalence of Syphilis, Scrofula, and Consumption.

Agency.	Syphilis.	Scrofula and Consumption.
Yankton, Dak.	"Have never seen or treated any kind of venereal disease."	"Scrofula is the one fatal disease among these Indians; every Indian in the reservation is more or less affected by it. Consumption prevails to a large extent."
Sisseton, Dak.	"Neither syphilis, gonorrhœa, nor chancroid exists among these Indians."	"Consumption and scrofula have always existed, and to a very large extent."
Devil's Lake, Dak.	"Only a few cases of venereal diseases among these people."	"Consumption and scrofula prevail, and one-third of adult deaths are from them."
Green Bay, Wis.	"In three years have treated no primary or constitutional syphilis."	"Consumption causes fifty per cent. of all deaths."
Tulalip, W. T.	"Venereal diseases comparatively rare."	"Consumption prevalent to a great extent, proportion of fatality due to it about fifty per cent. Scrofula among children is prevalent to large extent."
Standing Rock, Dak.	"Venereals prevail but slightly."	"Consumption and scrofula prevail to enormous extent, and are chief cause of death."
Lower Brulé, Dak.	"Venereals are rare. I have not seen a case of Hutchinson's notched teeth . . . or other evidence of hereditary syphilis."	"Consumption prevails to alarming extent. Scrofula is present in sixty per cent. of Brulé Sioux under twenty-one years of age. I have seen scrofula and syphilis in same individual."
Osage, I. T.	"Free from venereals."	"Consumption and scrofula prevail; ten to fifteen per cent. of deaths due to them."
Crow Creek, Dak.	"Venereals are very rare; no history of their prevalence at any time."	"Consumption and scrofula quite prevalent; fifty die from them every year in population of 1,200."
Cheyenne River, Dak.	"Venereal diseases are rarely seen."	"Consumption and scrofula are the prevailing diseases." —Agt's Rep, 1878.
Western Shoshone, Nev.	"The venereals do not exist to any extent worth mentioning."	"Consumption and scrofula prevail to quite an alarming extent; probably fifty per cent. of deaths are due to them."
Hoopa Valley, Cal.	"Venereals prevail to great extent."	"Consumption very rare, only two or three per cent. of deaths due to it. Scrofula is rare; only present when due to syphilis transmitted from parents." (The writer supplements his facts with his theory.)

[1] Transactions of the American Medical Association, 1878.

These facts speak for themselves; it is seen that scrofula may be enormously prevalent where syphilis is unknown, and that scrofula may not be found in those tribes which are thoroughly inoculated with the venereal poison.

I, however, cannot affirm too positively my assent to the belief that syphilis decidedly increases the vulnerability of the constitution to scrofula and tubercular consumption, and that, on the other hand, struma decidedly decreases the resistance of the system to the invasion and ravages of the venereal poison.

"Consumption in these people," writes Dr. Fred. Treon, of Crow Creek Agency, Dak., in a paper read before the Dearborn County (Ind.) Medical Society, 1887, "appears in the adults to follow an acute attack of bronchitis or catarrhal pneumonia; while usually the first symptom to which your attention is called in the child is a looseness of the bowels, amounting at times to dysentery; at first the mesentery alone appears to be affected, but later on a cough sets in, dulness on percussion is perceptible over one or sometimes over both lungs at apex, and not infrequently at base, mucous and crepitant râles are distinctly heard. Expectoration of a tough mucous character, and often frequent and copious hemorrhages are present. I have never seen them with a chill. The patient sinks rapidly and dies from asthenia." This presents a true picture of the course of the malady. I may observe, however, that I have rarely seen copious hemorrhage, and when hemorrhage is a notable symptom I expect the disease to pursue a much less rapid course. In many of my cases a continued fever, hectic, was the first feature to attract attention, which fever, with the attendant diarrhœa from tubercular involvement of the intestinal canal, presents an *ensemble* of symptoms exceedingly difficult of diagnosis in the early stage from typhoid fever.

It may be observed that the form of pneumonia prevalent among Indians is almost exclusively catarrhal; of the croupous or lobar form I have not seen a single case in two winters' practice.

In my practice in the school on this reservation, in the winter of 1877–78, I was impressed with the fatal *influence of exposure* toward the production or excitation of tubercular diseases.

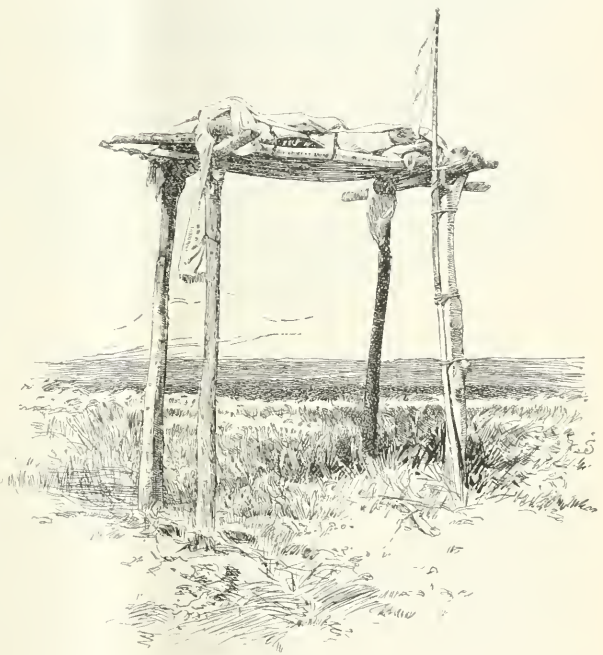
The girls were kept carefully indoors during inclement weather, and not one suffered a day's serious illness. An unusually severe winter required great exposure on the part of the boys in "drawing" fuel, and other out-door work. Of the boys, during the winter, one died of miliary tuberculosis, one of tabes mesenterica, one of pulmonary tuberculosis, and another never recovered from a severe catarrhal pneumonia, wasted, and died the next autumn. There was absolutely no difference in hygienic condition of boys and girls as to heredity, diet, dress, dwelling, etc., save only that the girls were protected from the severe and suddenly changing weather and the boys exposed to it.

The impression prevails pretty generally among the physicians of the Indian Service that *climate* exerts a very small influence on phthisis found among Indians. It is at any rate found in all climates, even those famed as being the most salubrious. My observations lead me to believe that it prevails most disastrously in the parts of the Northwest lying in Montana and Dakota. The climate of this region is dry and pure, the country being elevated and without stagnant water, or the elements of vegetable decomposition. It is found favorable to invalids of the white race coming into it. Several cases of phthisis have, under my observation, been held in abeyance.

So dry and pure indeed is the atmosphere that in scaffold and tree burial, as shown in the illustration, and which is the general custom of Northwest Indians, the bodies seem to dry and disintegrate without the usual evils of decomposition.

Of the tubercle bacilli I have said nothing, since I have been without the means of pathological investigation and could present only deductions from the facts presented, and others may draw such deductions as well as I.

Since writing the above paper I have received from the authors three valuable reprints bearing on these subjects: "Consumption among the Sioux Indians," by Dr. Fred. Treon, of Crow Creek Agency, Dak.; "Scrofula among the Sioux Indians," by Dr. Joseph B. Graham, Lower Brulé Agency, Dak., published in *American Practitioner and News*; and "Further Contribution to the Study of Consumption among the Indians," by Dr. Washington Matthews, U. S. A.



Scaffold Burial.

Dr. Treon lays stress on the probable causative relationship of beef-eating and milk-drinking to consumption. He then describes the slaughter. "Saturday, early in the morning, the cattle are shot down in the corral and the Indians drag them out, skin, and cut them up. I have observed them frequently, while slaughtering, eating the warm liver, tallow, and often the entrails, and great quantities of raw beef. In fact, much of the beef is dried, pounded up, and eaten without cooking. Frequently they eat animals that have died of disease days before, and to my mind here is a good solution of the trouble." The doctor has on several occasions seen steers with "big-jaw," or actinomycosis, received and killed for the Indians, and in this also he sees a ready method of infection. His picture of the slaughter is absolutely true, as I have many times seen it; and concerning the actinomycosis I may add that it is the constant custom for cattle-men driving their herds across Indian reservations to placate the In-

dians by cutting out and giving them all "big-jawed" steers, such being unmarketable, and so of no value to the owners.

The doctor suggests the following method of infection: "It would not be difficult to trace these microbes from the stomach to the mesenteric lymphatics, and even through the circulation to the lungs. Entering the blood with the chyle through the thoracic duct, finding their way through the left subclavian vein to the heart, whence they may be sent with the blood to the lungs, where a nest or home is often found for the parasite. Bartholow says ('Practice of Medicine'), every germ needs a specific soil for its growth, so the specific infective material of consumption must fall into a properly prepared organism to proceed to full development. It is needless for me to say that the mesenteric glands and lungs of these people are a well-suited soil for the bacilli of tuberculosis."

Tree Burial.

"Supposing that only one out of a thousand cattle received be affected with tuberculosis or actinomycosis, from the manner of dividing the beef it is possible, and probable, that one hundred persons may become inoculated by a single diseased animal."

The practical deduction from these theories, which are supported by many respectable names, is that greater care should be exercised by the Government in the inspection of beef and milk cattle received for Indian tribes, and the proscription by the same authority of giving of diseased cattle to Indians by cattle-men grazing on reservations or driving over them.

Dr. Graham accepts the unity of scrofula and tuberculosis, considering the former the manifestation usual in the child, the latter in the adult; he does not admit a venereal causation, but is of the opinion that syphilis is a distinct disease and can only be reproduced as syphilis.

In his tribe of less than thirteen hundred people, in two years, he treated thirty-two severe cases of scrofula, and by actual count at one time found two hundred and five, mostly under eighteen years of age, suffering from a less severe form of scrofula.

Dr. Graham also appreciates the danger of infection from cattle, and states as a fact noted by Alex. Rencountre, that the first case of scrofula among the Brulé Sioux occurred in 1869; that beef cattle were first delivered to these Indians in 1869. He urges the frequent violent epidemics of measles, with the resulting bronchitis and catarrhal pneumonia, as a powerful predisposing cause of consumption, to which I should like to add strong personal testimony. The effects of the "transition," of which I have written on previous pages, but with less force and conciseness than Dr. Graham in his valuable paper, is thus described by him:

"In the normal and uncivilized state the principal diet of the Dakotas was buffalo meat, the supply of which, only in exceptional times, was very plentiful. Their 'tipis' were made of buffalo skins, were well ventilated, and offered ample protection from the weather. Their clothing, of the same material, was sufficient for their needs. How do we find the Indians of to-day? Instead of the comfortable skin tipi, they now inhabit one of unbleached cotton which offers no protection from the cold of winter or dampness of the rainy season; or to the other extreme, a log cabin, with dirt floor, plastered till almost air-tight. Light is admitted through a single window, without any ventilation whatever. These houses are kept in winter at a temperature from eighty to ninety degrees Fahrenheit, and inside are practically dry at all times. Exhalations from persons and dogs, with sputa from consumptives and pus from scrofulous sores, are allowed to lodge in the walls and dirt floor. They are rapidly dried by the high temperature and suspended in the atmosphere of the room. Thus it may be seen that these houses are the greatest source of danger; veritable culture-soils and hot-beds, they furnish the best possible condition for the spread of tuberculosis when the bacilli lodge in the soil prepared for them by exposure, under feeding, and malnutrition. Not only is death lurking in the air of these places, but as the raw beef, sliced, is hung there to dry in winter, tubercle bacilli or spores may lodge in the beef, and as this is often eaten raw, another most formidable source of danger to others and of self infection presents itself."

I trust that this invective, added to my own, against the "house" built by themselves or built for them by the Government, may be seed to fall in good ground, and bear the fruit of houses better suited to their needs and less perilous to their health.

A New Parasite in Cancerous Growths has been discovered by Drs. M. A. Ruffer and J. H. Walker (*British Medical Journal*). The discovery has been confirmed by Professor Metschnikoff. The parasite consists of a central nucleus, that is, of a central part which, according to the reagent used, takes up the stain more deeply than the remainder of the body, or else stains quite differently from it. This nucleus apparently does not possess a distinct membrane. From certain staining reactions it appears that the substance forming the nucleus resembles in its chemical reactions the nucleolus of the invaded cell, though there are certain points of difference between them. Around the nucleus the protoplasm is condensed (?) and from this centre extremely fine, delicate rays often extend to the periphery of the organism. One might then think that the parasite consisted of the nucleus and central mass of protoplasm, furnished with long pseudopodia; but careful observation shows that these rays terminate at the periphery, and are continuous with the rounded outline of the parasite.

ADENOIDS IN THE NASO-PHARYNX IN CHILDREN.[1]

By T. H. HALSTED, M.D.,

AURIST AND LARYNGOLOGIST TO FREE DISPENSARY, SYRACUSE, N. Y.

MR. PRESIDENT AND GENTLEMEN: There are few subjects of equal importance which are less discussed than this of post-nasal growths in children. There are few diseases so easily diagnosed, the early recognition and treatment of which would prevent so much subsequent trouble. If the statement be true that adenoid growths in children is by far the greatest cause of middle-ear disease and deafness (in children), the importance of diagnosing and treating this condition before it has worked irreparable mischief will be admitted. It has been the misfortune of otology that the ear has been viewed too much through the aural and too little through the nasal speculum and rhinoscopic mirror.

Czermak, in 1860, without appreciating his discovery, was the first to see in the naso-pharynx two small vegetations. In 1865 Lowenberg and Voltolini each saw these vegetations in a few cases of middle ear disease, and believed them to be the cause of the middle ear diseases with which they were associated. It was not, however, until Meyer, of Copenhagen, in 1868, had published his paper, based on one hundred and seventy-one cases of adenoid growths which he had found in school children, that the attention of the profession was at all directed to this newly discovered disease. That even otologists did not fully appreciate the relationship between middle-ear disease and adenoids is seen by the very scant reference to it in text-books of the ear, published prior to the past six or seven years. In the last edition of "Burnett on the Ear," published in 1884, and consisting of 576 pages, less than one is devoted to this subject. An excellent little work on the ear, by Pritchard, published last year, and consisting of only 210 pages, gives 7 of them to this disease. Cohen, in his book on the "Nose and Throat," published in 1879, gives 11 of the 711 pages to this subject, while Bosworth in his last work devotes one-twentieth of the whole book to adenoids, or, as he prefers, "Hypertrophy of the Pharyngeal Tonsil."

The term "adenoids" is the one most frequently employed, but is inferior to that of "hypertrophy of the pharyngeal tonsil," as the latter name at once conveys the conception of the true pathological condition. The vault and posterior wall of the naso pharynx are more or less covered with a glandular or lymph tissue, similar to the faucial tonsils, and called the pharyngeal, third, or Luschka's tonsil, after Luschka, who first described it. The main function of this, as of other tonsils, Lenox Browne says, is "probably that of the manufacturing of leucocytes to act as phagocytes or scavengers for the clearing away of food débris and for the holding in check of micro-organisms in the upper respiratory and alimentary tract;" while Bosworth thinks the chief function is the secretion of mucus for the purpose of lubricating the food to make its downward passage easy, the mucus being constantly secreted and passing to the lower pharynx, where it comes in contact with the food. The microscopical appearance of a section of these so-called adenoids shows them to be a true hypertrophy of the lymph tissue, *i.e.*, of the normal pharyngeal tonsil, very analogous to that of an enlarged faucial tonsil, the latter differing only in its greater amount of connective fibrous tissue. The reason of the enlarged faucial tonsil being firmer and containing more fibrous tissue is because of its location in the food tract, where it is subject to almost constant irritation and pressure. Just as in the fauces we see enlarged tonsils of different degrees, some only slightly enlarged, then again others so large as to meet in the centre and shut off the view of the pharynx, in the same way do we see adenoids of different degrees of enlargement. They may be slight and apparently of no injury, or they may be so large as to fill the whole post-nasal space. It is when they become sufficiently enlarged as to interfere with nasal respiration or by their position occlude the Eustachian orifice that they become of pathological importance calling for treatment.

During the past three months I have carefully examined 268 children to ascertain how many of them had this condition of adenoids sufficient to cause mouth-breathing. These children were from five to fifteen years of age, and all institution children; 116 were of the State Institution for Feeble-Minded Children; 154 belonged to the Onondaga County Orphan Asylum. As a class they are more predisposed to glandular or lymphatic disease than other children, and the percentage of cases of adenoids found among them is doubtless much greater than we would ordinarily meet with—possibly as large again. In all I examined the nose, mouth, pharynx, and naso-pharynx, using the rhinoscopic mirror in the latter, and noted the conditions found. The night attendants then observed the children while asleep, and reported on each one separately as to whether or not it slept with open mouth, snored, etc. I then compared their reports with my examination, and give the result in the following table:

REPORT.

Asylum for Feeble-Minded Children.

Number of children examined, 114.

Boys	61.	Ages 5 to 10 = 45
Girls	53.	Ages 10 to 15 = 69

Number with adenoids sufficient to cause mouth-breathing, 23, or 20.1 per cent.

Boys	10.	Ages 5 to 10 = 9
Girls	13.	Ages 10 to 15 = 14

Onondaga County Orphan Asylum.

Number of children examined, 154.

Boys	95.	Ages 5 to 10 = 103
Girls	59.	Ages 10 to 15 = 51

Number with adenoids sufficient to cause mouth-breathing, 40, or twenty-six per cent.

Boys	29.	Ages 5 to 10 = 31
Girls	11.	Ages 10 to 15 = 9

Total number children examined, 268. Total number children with adenoids, 63, or 23.7 per cent.; associated with enlarged tonsils, 32, or fifty per cent.; with some anterior nasal obstruction, 29, or forty-six per cent.

Heredity as a predisposing cause is, I think, a potent factor in the development of these growths—not an hereditary predisposition to adenoids particularly, but of an inherited tendency to all glandular inflammations. The acute attacks do not fully resolve; there is a strong tendency for the condition to become subacute, and then chronic. It is in these children that we are likely to find enlarged submaxillary and cervical glands. They are to a great extent of a diathesis which, for want of a better name, we call strumous. This is shown very well in the result of my examinations, as the class of children, as a whole, would be said to be largely strumous, and among them we find more than twenty per cent. showing chronic enlargement of the pharyngeal tonsil.

Age is another predisposing cause, because in children the lymphatic glandular tonsillar system is the one most prone to inflammation. As a rule, when a child has a cold in the head it takes the form of an acute naso-pharyngitis, instead of, as in adults, an acute rhinitis. Probably from three to ten is the period most likely for the development of the growths. Undoubtedly they occur much earlier, and just how early they may begin we cannot know. I recently operated on a child, for this disease, twenty-two months of age. They occur less frequently after puberty, though they are often found as late as between thirty and forty years, and even later. A great many direct causes are given in all text-books, but simmered down they are two, viz., repeated acute inflammations, and some obstruction in the nose. As causes of the acute inflammation are climate, such as ours, the ex-

[1] Read before the Onondaga County Medical Society, Syracuse, N. Y., April 19, 1892.

anthemata, whooping-cough, diphtheria, etc. Of my 63 cases some anterior obstruction was found in 32; of the 40 cases at the Orphan Asylum, 18 showed some form of obstruction, an hypertrophy of the turbinateds, deviations or thickenings of the septum, or a depressed tip; of the 23 cases at the Idiot Asylum, 11 showed the same kind of obstruction, but in nearly all of them was there a very narrow and high-arched palate, which acted by raising the floor of the nose, and to that extent diminishing the respiratory capacity of the nasal cavity. In none of these was the obstruction sufficient to prevent nasal respiration, but enough to impair it to a greater or less extent. MacDonald explains the *rationale* of the production of adenoids as a result of some anterior hypertrophy in this way: that where there is an obstacle causing some stenosis in the nose, and where nasal respiration goes on, the barometric pressure behind the obstruction is diminished, an overfilling of the blood-vessels results, and it in its turn —through vaso-motor disturbance—leads to hypernutrition and hypertrophy of the tissues behind the obstruction, and in this way is hypertrophy of the pharyngeal tonsil produced.

The nose is the organ of smell and the beginning of the respiratory tract. In normal respiration the inspired air in passing through the nose becomes filtered of particles of dust, etc., is completely saturated with moisture, and is heated to a temperature of about 95° F., no matter what the external temperature of the air. There is as well an exchange of oxygen and carbonic acid gases. These respiratory functions of the nose at once demonstrate the great importance of breathing through this organ. There is, however, one other extremely important purpose of nasal respiration—I mean ventilation of the middle ear. The Eustachian orifice in the naso-pharynx is just behind the posterior end of the inferior turbinated body, and in the direct current of respired air. In inspiration the air must reach the larynx either by the nose or mouth. Obstruction to nasal breathing must be above the pharynx as seen from the mouth, *i.e.*, either within the nose or naso pharynx. In children it is almost always within the naso pharynx, in adults within the nose. In proportion to the extent of the obstruction, mouth-breathing becomes a necessity. Mouth-breathing is never a habit, but a result and a symptom of nasal or post-nasal obstruction, and as a sequel of a long continuance of it we would expect to find, and usually do find, either a chronic pharyngitis, laryngitis, or tracheitis in the respiratory tract, or a chronic catarrh of the middle ear, or indeed all of these conditions combined.

The expression and voice of children the subjects of adenoids are so characteristic that one is almost safe in making a correct diagnosis on these two symptoms alone. The mouth is open, the lower jaw appears to drop, the lips are thick and expressionless, the root of the nose is broadened, giving to the eyes an appearance as if unusually wide apart; add to this the somewhat stupid expression that would go with such an appearance, but which is enhanced by the almost invariable defect in hearing that accompanies these cases, and you have an expression typical of adenoids. Examined more closely there is a depression on each ala of the nose, the nostrils are often small and narrow, making the bridge look unusually broad. This expression might lead one to think that among a certain percentage of feeble-minded children these growths stood in a relation of cause and effect, and it was with a view to seeing how true this was that I began my examination at the Idiot Asylum. So far as they go, my examinations showed that adenoids were not more prevalent among the Idiot Asylum children than those of the Orphan Asylum Whether adenoids can, excepting in very exceptional cases, be the cause of the weak mental condition found in what are known as feeble-minded children, is doubtful. Certainly the removal of these growths in a child said to be dull or slow very frequently produces a wonderful effect in changing it from a dull to a bright child. The speech is of a quality the Germans call "dead"—a thickness in which there is an impairment or entire lack of nasal resonance. The function of the vault of the pharynx as a sounding-board is abolished or much interfered with. The child may turn his m's and n's dependent upon the nose into b and d. The voice is peculiar and is quite different from that of enlarged tonsils or of a simple nasal stenosis. Snoring during sleep is a prominent symptom. It is not by any means always present.

As MacDonald says, the instinct of nasal respiration while asleep is so strong that children the subject of it only breathe through their mouths when absolutely compelled to. The following case illustrates this: The mother of A. B—— consulted me on account of the difficult breathing of the child while asleep. The patient, aged four years, was asleep about half an hour when I first saw her. Her forehead was bathed in perspiration, face deeply flushed, lips almost cyanotic, breathing so labored that epigastric recession was marked, her mouth was covered with a frothy saliva which was sucked in and out with each respiration through her teeth, which were closed. The dyspnœa was as great as that of many cases of croup. I found that on separating the teeth with a lead-pencil the dyspnœa was immediately relieved, and snoring began. This child, for over two years, would every night during the first half-hour or so of sleep breathe as I have described; she would finally turn over, or wake up and open the mouth and continue her sleep with mouth-breathing, and snore for the rest or greater part of the night. Not much wonder the child was pale, anæmic, and languid, easily tired out during the daytime. In a few days I removed the adenoids which were present, with the result that within three nights after the operation the child slept with closed mouth as quietly and easily as any child could. It is now four months since the operation, and during this time the child has not had a restless night. In this case there has been absolutely no other treatment since the operation. Snoring, noisy respiration with open mouth, or restlessness during sleep occurs in those cases where the adenoids are large enough to be an obstruction. One of these cases at the Idiot Asylum snored with its mouth closed, an unusual but not rare circumstance in children with adenoids. Other symptoms present in most cases are a large amount of muco-purulent discharge at the back of the pharynx, a good deal through the anterior nares, with an inability to blow the nose, pain over the brow, and a want of ability to concentrate the attention for any length of time. The most important symptom of all is the one most often overlooked. This is some degree of hard hearing, and it is frequently not until there is a discharge from the ear or the deafness is marked that the patient comes under our observation. For the proper performance of the ear, the middle-ear must be freely ventilated, and the membranum tympani have an equal air-pressure on both sides. If from any cause the external pressure exceed the internal, the membrane is driven in, it cannot vibrate properly, and a degree of impairment of hearing must result. In order that the ear be properly ventilated, respiration must be through the nose, otherwise the air in the naso-pharynx and middle-ear becomes, as it were, stagnant, an absorption of oxygen takes place from the air in the middle-ear, the air is rarefied, *i.e.*, the barometric pressure lowered, and to overcome this partial state of vacuum there is a rush of blood with an over-distention of the vessels in the mucous membrane lining the cavity. If long continued, this hyperæmia becomes chronic, and in time leads to a structural hypertrophy, and we have a chronic hypertrophic condition of the Eustachian tube and middle-ear, with which is the indrawn membranum tympani; with this there is a degree of deafness dependent upon the extent of the ear change. This explanation of adenoids causing middle-ear disease is, I believe, the true one in most cases; but there are two other ways in which they may give rise to the same result, viz., by their presence interfering with the free action of the dilator muscles of the Eustachian

tube, and by their situation directly occluding or pressing upon the orifice. This latter is the explanation usually given; but I believe it to be the exception, because it is the exception to find the growths directly impinging upon the orifice. They are often so situated, and when so would account for those cases of otitis media due to adenoids where the growths are not large enough to be an obstruction to respiration. This symptom of deafness or hard hearing is not always manifest to either patient or parent. It is seldom, in those cases where the parent is positive there is no hardness of hearing, that you fail to elicit the statement that the child is inattentive both at home and at school. On questioning he may give a history of repeated earaches. Recently a father insisted that his boy heard perfectly, being only a little absent-minded or inattentive, but a test of hearing showed that he heard with the watch with one ear ten feet, with the other eleven inches. The membranum tympani was markedly retracted on the bad side. As to the frequency of middle-ear disease in adenoids, Meyer found seventy-four per cent. of his cases had some demonstrable degree of hard hearing or deafness. Woakes says ninety-five per cent. of his cases had middle-ear disease. Undoubtedly a very large per cent. show ear trouble, varying from a slight beginning catarrh to a suppurative otitis media with necrosis of the bones and formation of polypi. On the other hand, the majority of middle-ear cases in children show the presence of adenoids. Owing to the nature of my cases and lack of time, I was unable to make any accurate examination with regard to ear complications.

There are two ways of examining the naso-pharynx for these growths. The best is with the rhinoscopic mirror. Nearly all text-books insist on the impracticability of this because of the patients being children. I was enabled to satisfactorily examine over eighty-five per cent. of my two hundred and sixty-eight examinations with the mirror, and think patience, perseverance, and getting the child's confidence will work wonders in overcoming gagging and retraction of the soft palate. As seen by the mirror they are of varying appearances, according to their size and location. Usually of a pale pink or grayish pink color, or at times dark red, they are seen to project from the posterior and upper surface of the space like a cushion, that is dented in, or furrowed longitudinally, forming two to five or six lobes. Again, they may so completely fill the naso-pharynx that the usual landmarks of the choanæ are lost, and apparently one sees only an irregular pale mucous membrane without any shape or form of a tumor. At times they hang from the vault extending across it like a cock's comb, or they form a fringe around the Eustachian orifice and fill up Rosemüller's fossa. They may extend so low as to be seen below the soft palate and require only the tongue-depressor to make out the lower portion.

The other method of examining is by the finger. Standing behind and to the patient's right, the left forefinger, protected, is inserted between the jaws of the left side as a gag, and the right forefinger is carefully passed back of the right tonsil, turned upward along the posterior wall of the pharynx behind the velum palati. The sense of touch imparted is characteristic, being described as feeling as if the finger were among earthworms, or it is not altogether unlike the sensation produced by sticking the finger into mush. By this examination we can determine the size and location of the growths. It is disagreeable, suffocative, but need not be painful to the patient. A little blood usually comes away on the finger. In most of my sixty-three cases, a condition of follicular pharyngitis was present. The follicles are enlarged, pale pink, look sluggish, and are practically of the same nature as the adenoids, and not to be confounded with the granular pharyngitis of adults. Enlarged tonsils are not always present with these post-nasal growths, but I doubt if adenoids are not nearly always present where we find enlarged tonsils. What was formerly attributed to enlarged tonsils, such as faulty nutrition, pigeon breast, stupid facial expression, etc., is now usually conceded to be the result of the presence of adenoids in the naso-pharynx. In my sixty-three cases, enlarged tonsils were present in over fifty per cent. They are the result and not the cause of adenoids, and as an explanation would suggest that a continual mouth-breathing would predispose anyone to acute tonsillitis, and more particularly those children who are already predisposed to glandular and tonsillar inflammations. Repeated attacks soon leave a subacute and chronic condition with a subsequent permanent enlargement. As indicated, in speaking of the etiology in most cases we find some trouble in the nose. In a number I found the sole anterior trouble a sunken, depressed tip, obliterating, to a certain extent, the nostrils. The other obstructions were deviations and thickenings of the septum, enlarged inferior turbinated, and high arched palate. If left to themselves they are said to undergo atrophy after puberty, and for this reason some men advise leaving them alone. Doubtless they do become smaller, but the naso-pharynx becomes larger at about this period, and the seeming decrease in size of the adenoids is often more apparent than real. Patients do not come to us to be treated for post-nasal growths, but for some symptoms or pathological conditions produced by them, and in these cases an active treatment is necessary. The prognosis is then good, both as regards removal of the growths and of the conditions produced by them. If left alone they may shrink as years advance; but while they are undergoing a "spontaneous recovery," the ear may suffer an active change too, and deafness result from this expectant treatment.

Treatment.—Not all cases require treatment, but those do which cause mouth-breathing, or middle-ear disease. There are three methods of treatment—the local application of caustics and astringents, the galvano-cautery, and the surgical removal. Chemical caustics and astringents are very unsatisfactory and are of little avail. Where surgical means are not permitted by the patient, the galvano-cautery is much preferable to chemical caustics, as chromic and tri-chloracetic acids. An electrode, properly curved, is introduced into the naso-pharynx under the guidance of the mirror, and several points cauterized. A number of sittings are necessary. Cocaine does not completely anæsthetize, and it is in very exceptional cases that one would use the galvano-cautery. I cannot see how it could be used with small children. By far the best treatment is the surgical removal, and all who have had much experience are agreed in this. Many different kinds of forceps, curettes, and snares have been devised. A few use the snare introduced through the nose, or, as Bosworth does, through the mouth. For practical purposes it is far inferior to cutting instruments. The instrument which I use and prefer is Juracz's modification of Lowenberg's forceps. It consists of a cutting forceps, properly curved to be introduced through the mouth into the naso-pharynx, and has a lateral movement, the posterior and upper surface of the inner side of each blade having a cutting edge to meet its fellow, the anterior edge being non-cutting and concave, to prevent injury to the septum or soft palate. In children, but not in adults, I think a general anæsthetic necessary, and I give ether. The operation, though short, is a painful one, and better and more thorough work can be done than where the child is fighting you. With the child on its back, a proper gag, such as O'Dwyer's, well back between the jaws of the left side, the operator standing on the right, the left forefinger is introduced back of the soft palate, to act as a guide for the forceps, which are introduced with the right hand. The adenoids are removed in pieces, from three to six introductions of the instrument usually being required. After the forceps has removed all it can, it is well to introduce the forefinger and with the nail tear away any small pieces that may remain about the Eustachian orifice, or in Rosemüller's fossa. The hemorrhage following is quite copious and sharp, but lasts but a few minutes, and the mouth and pharynx sponged, the child turned on its side and face, the blood escaping through the nose and mouth, there is little danger

of its reaching the larynx. In a certain number of the flat variety, the forceps does not answer, and here a curette, such as Gottstein's, becomes necessary. When this instrument is used, the patient sits upright, cocaine is used as an anæsthetic, and the operation done under a good light. In any of these operations, wounding of the Eustachian orifice, fracturing of the vomer, or stripping the mucous membrane from the soft palate, are to be avoided. Fortunately, as a general thing, no further treatment is necessary beyond the use of an alkaline antiseptic spray for about a week, the result being after three or four days a striking and marked improvement, and relief of all signs of obstruction. In those cases, however, in which there is some anterior nasal obstruction which may have had a good deal to do with the causation of the adenoids, the treatment will not be entirely successful until its removal.

LACERATION OF THE PERINEUM: ITS EFFECTS AND CAUSES.[1]

By S. M. VORIS, M.D.,

COLUMBUS, IND.

It is not my purpose on this occasion to endeavor to present a detailed consideration of perineal lacerations after the manner laid down by authorities; neither is it my purpose to try to coincide with or claim the support of authorities. Consequently, in offering what I do for present discussion, and the test of future observation, I do not challenge discussion based on your knowledge of the books, but I do appeal to your own practical observation guided by natural law, common sense, and reason. To begin, I feel confident that it is only necessary to appeal to your every-day experience to establish the fact that lacerations of the perineum are humiliatingly frequent. While we sometimes hear physicians boast of having never had perineal rupture under their care, we frequently know, as a matter of fact, that they are either guilty of gross carelessness in not knowing, or grosser deception in trying to conceal, the existence of a laceration.

Whatever statistics might reveal, if they could be correctly gathered, it is sufficient for us to know that, in our every-day duties as physicians, we meet with a sufficient number of women dragging through a weary existence as a result of old cicatrized lacerations and their resultant evils, and a sufficient number of new ones occurring to help us to realize that they stand out as a sad commentary on the boasted skill of modern midwifery.

The usual evil results which may follow this accident, immediately or remotely, as given by the books, are prolapsus vaginæ, with cystocele or rectocele, prolapsus uteri, incontinence of fæces and intestinal gases, and cervical metritis, etc. Of course, these evils vary in frequency and extent according to the extent and character of laceration.

While authorities have hitherto agreed that the limited lacerations are followed by little or no inconvenience, it seems more consistent with my observation that some of the most reputable teachers of the present day are beginning to emphasize the point, that any extent of lacerated and cicatrized perineal surface exerts a direct influence upon the sympathetic nervous system, which is more prolific of evil even than lacerations of the cervix-uteri.

As we now come to the consideration of the causes of this accident, it is my purpose to mention some of those only which operate in connection with the parturient act. And these are mentioned not to invite discussion on this occasion, but for easy reference in connection with a cause I shall endeavor to demonstrate further on. Not that I would detract from the value of the causes as presented to us by authorities, but that I may be able to emphasize the special object or purpose of this paper.

We are taught that the accident may arise from a deviation from the ordinary mechanism of labor—from mal-conformation of the passage or soft parts, from malpresentation or mismanagement. 1. If the sacrum be too perpendicular, the head of the child, instead of receiving a direction anteriorly in the line of the axis of the lower outlet, will be forced downward upon the posterior portion of the perineum. 2. If the subpubic arch is so acute as to prevent the presenting portion from filling its upper part, etc.

I doubt not in the experience of many of you there have occurred perineal ruptures where there appeared to be no perceptible deviation from the normal mechanism whatever, and when it was a difficult problem to determine why such laceration should occur at all. In the solution of this problem I wish to call attention to a hitherto unrecognized force, or indirect influence, manifested in the mechanism of labor, which I believe is responsible indirectly for more lacerations of the perineum than all other causes combined, operating in connection with the parturient act.

The mechanism of labor is defined to be "a combination of movements founded upon the principle of adaptation, and intended, through the proper adjustment of the respective diameters of the fœtus to those of the pelvis, to facilitate the passage of the former into the world."

These movements are usually given as four—by some authorities five, viz.: flexion, descent, rotation, and extension, with sometimes external rotation or restitution.

We will consider, for the purpose of illustration, this combination of forces and movements as they are manifested in an ordinary natural labor, in the first vertex position.

In this position the occiput, or the posterior fontanel, corresponds to the left acetabulum. Under the influence of the uterine contractions transmitted through the spinal column, the occiput advances and the chin is thereby brought in close approximation with the sternum, constituting the movement of flexion. You will please note the fact that this movement is explained by the fact that the articulation of the spinal-column with the head takes place considerably posterior to the centre of head; consequently flexion takes place in obedience to a very natural law—easily comprehended.

In obedience to the continued contractions of the uterus the head now descends into the pelvic cavity, adapting itself to the course of least resistance, and, influenced by the inclined planes, the occiput is brought to a position corresponding to the symphysis pubis and the face in the concavity of the sacrum. This constitutes the movements of descent and rotation.

We have now come to the movement in the mechanism of labor which has a special significance in the purpose of this paper.

We are told that from its peculiar position at the lower strait after rotation is effected, the posterior surface of the child's neck is brought closely against the symphysis pubis, which becomes a point of resistance, so that the force of the uterine effort, which until this time had fallen on the occiput, is now concentrated on the chin, which causes it to leave the sternum and sweep over the perineum, thus completing the movement of extension and the second stage of labor

I have tried to quote in substance the usual description of these movements. The movement of extension is usually passed over with very few words, signifying that it is simple and easily understood; and some prominent teachers of the present day ignore it entirely, disposing of it along with rotation by stating simply that the head seeks the course of least resistance, etc.

Now, right here I will state emphatically that I have never accepted the philosophy of extension as taught by the books, for the simple reason that it does not appear consistent with natural law, nor with common sense and reason. I do not believe that the force of the uterine contractions, as conveyed to the head through the spinal

[1] Read before the Indiana State Medical Association.

column, is the real cause or has anything immediately to do with the movement of extension. Consider for a moment: The atloaxoid articulation is pressed closely against the point of resistance, the sub-pubic arch. The occiput is comparatively free, but the frontal region and chin, the most distant parts from what is considered the point of resistance, are expected, in obedience to a force received almost exactly at that same fixed axis, to revolve around that axis, notwithstanding the resistance that we know by experience is presented by the perineum. It seems to me to be expecting too much of human credulity. I am firmly convinced that here, in this movement, is to be found the key to the secret of the greatest danger to the integrity of the perineum.

The question then naturally arises: What is the true philosophy of the movement of extension? and how does it affect the perineum?

In endeavoring to demonstrate to you what I conceive to be the true philosophy of extension, I shall begin by appealing to an old and long-accepted natural law, which I believe has never been repealed, namely: Action and reaction are equal and opposite. We are told that when the uterus contracts there is a shortening of its longitudinal fibres. Now, in the beginning of this stage of labor, when the os uteri is undergoing dilatation, it furnishes a certain amount of resistance, which, together with the resistance of the head against the circumference of the superior strait, compensates the force exerted by the contracting uterus. But when the uterine contractions have forced the head down into the pelvic cavity, it has at the same time, by shortening of its longitudinal fibres, retracted the rim of the os over the head. Consequently, at the beginning and during the movement of extension, in the absence of the resisting os, the reaction or purchase must necessarily come from the tension of the vagina, and finally from the resistance of the perineum as conveyed through the vagina.

There is no other connection of force between the uterus and perineum except through the walls of the vagina, consequently, when the head is resting against the perineum, and the uterus by its contractions shortens its longitudinal fibres, and thereby shortens its connection with the perineum, the latter must necessarily furnish the resistance, or the uterus would recoil; for action and reaction are equal, and the uterus has no other stay except the broad ligaments and abdominal pressure, which may have little or no influence whatever.

Now, at the beginning of the movement of extension, when the posterior surface of the neck is in contact with the subpubic arch, the shoulders resting behind the arch, and the head is pressing on the perineum, the shortening of the longitudinal fibres of the uterus, instead of forcing the body of the fœtus down, fails to overcome the resistance of the shoulders and neck against the arch, and consequently the vagina and perineum become the movable points, and are retracted over the head just as the os uteri was in the first part of this stage of labor.

When the inclined plane of the perineum formed by the curved posterior columns of the vagina becomes tense, through the contraction of the uterus on the one hand, and the resistance of the perineum on the other, the head does not, or it should not, advance, but is forced toward the symphysis pubis, while at the same time the perineum is pulled back over the head, constituting the movement of extension without excessive distention of the perineum. During this movement the quieter the body of the fœtus remains, the greater is the safety of the perineum. Then the shoulders change position, and the second stage of labor is completed.

Owing to the peculiar anatomical construction of the vulva the tension caused by the fœtal head falls entirely on the posterior commissure, the resistance anteriorly being furnished by the subpubic arch. In the latter months of gestation the integument is sometimes so tense over the abdomen that the vulva is drawn up over the symphysis, bringing the vaginal orifice and posterior commissure closely beneath the arch, thus serving as another element in the resistance of the perineum.

In the light of this philosophy of the movement of extension it follows as a natural sequence that any cause operating against the proper tension of the posterior columns of the vagina will seriously interfere with the perfect extension of the head, and any cause interfering with extension will seriously endanger the integrity of the perineum.

An unyielding or rigid os may cause the uterus to be forced down into the pelvis by the abdominal tenesmus, before the head is relieved of its resistance, and the rim of the os or anterior columns of the vagina so retained between the head and subpubic arch as seriously to interfere with the proper tension of the posterior columns of the vagina.

A perpendicular sacrum, spoken of by authorities, rendering the central curved line of the pelvic excavation more obtuse, tends to relax the posterior wall of the vagina and allow the tension to fall upon the anterior wall.

Neuralgic or false labor pains attended with the expulsive effort, sometimes produce an effect similar to that of a rigid os. Ergot, by exciting the circular out of proportion to the longitudinal fibres of the uterus, and by the continued and unremitting character of the contractions produced, tends to an unsafe labor.

These causes, and probably others, operating singly or combined, may render an auspicious termination of labor extremely doubtful. And while it may not always be possible to determine the cause, it is sufficient for me to repeat that it is my firm conviction that any cause which may prevent the posterior columns of the vagina and the perineum from receiving the tension caused by the contractions of the uterine longitudinal fibres, will allow the head to descend upon the back part of the perineum in a flexed or partially extended condition, which, in the absence of the support and influence of the tense inclined plane, formed by the posterior wall of the vagina, gives way before the descending head and pouching back of the sphincter vaginæ, and renders a perfect and safe extension almost impossible.

When approaching this point in the second stage of labor, if I find the posterior columns of the vagina tense, and the posterior commissure well drawn back, probably as far as the anterior fontanel, in the first position, I feel comparatively content to allow labor to proceed without interference. But if the vaginal orifice is drawn up more or less closely beneath the subpubic arch, and the walls of the vagina are lax and corrugated in front of the descending head, I immediately place the patient on her left side, with the thighs well flexed upon the abdomen and the shoulders forward, in what is tantamount to the Sims position. This tends to throw the fundus forward and change the planes and axes in a way that renders the vaginal curve more acute; then sitting with the left side to the back of the patient, supporting the knees against the abdomen with the left hand, I place the right open palm over the perineum and posterior commissure, not only in obedience to the time-honored injunction to "support the perineum," but to assist in retracting the perineum; for the perineum must retract, and that, too, before the head is forced down, or mischief is liable to be the result.

The first examination after the change of position will usually reveal a decided change in the condition of the perineum. Should this procedure fail, I then resort to forceps, but not for the purpose of traction. I apply them with the handles well back against the commissure, then, with the right hand making sufficient pressure to prevent the instrument slipping, and with the left open palm applied firmly over the perineum, I simply raise the head toward the symphysis, at same time pressing the commissure back over the head.

Of course, circumstances and conditions may change or affect the feasibility of these procedures, but these are sufficient to indicate the idea I wish to convey.

DANGERS OF INTESTINAL INVAGINATION SUBSEQUENT TO OPERATION.

By FRED. BYRON ROBINSON, B.S., M.D.,

CHICAGO, ILL.,

PROFESSOR OF GYNECOLOGY IN CHICAGO POST-GRADUATE SCHOOL; ATTENDING SURGEON TO WOMAN'S HOSPITAL AND GYNECOLOGIST TO CHARITY AND POST-GRADUATE HOSPITAL.

INTESTINAL surgery is about the most dangerous and disastrous of all surgery. The reason is not far to seek, for the danger lies in the fact that all repair to the digestive tract must be done while its function actively resists. We have no means of putting the mucous membrane to an anatomical or physiological rest. It refuses to indulge in a furlough while its defects undergo repair. Not only that, but when it is in need of repair its very vitality at the seat of defect is lessened, and violent peristalsis in the proximal bowel enhances the dangers by further crippling the circulation and assimilation in the attacked segment. Repairing a gut is like repairing a watch while it is running. One is thwarted from beginning to end by persistent movement and function.

A well-known skilful English surgeon told me personally that he had killed grave-yards full of *people* (instead of dogs) in order to learn how to do intestinal surgery. I fully believed him, for during my visit to him he was still filling graves from defective intestinal surgery. Yet I can assure the reader that this very surgeon's name is the synonym of skill, but he happened to be working in a field where disasters occur. In giving practical intestinal courses to abdominal surgeons from various States, I have a good opportunity to note effects and defects of intestinal operations on living dogs. Surgeons will come for a course who have done some thirty consecutive laparotomies without a death, and they will do six to eight intestinal operations on living dogs, and occasionally half the dogs will die inside of a week.

Such proofs, with the experience of some two hundred and twenty-five intestinal operations on dogs, with the careful personal observation in almost every case of the autopsy, has well convinced me that intestinal surgery is about the most difficult in the whole art. Among the defects which I have noted for four years in the experimental work has been that of *invagination* subsequent to operation. Invagination of the bowel is the passing of a segment of the gut into that immediately adjacent to it. It is caused by irregular action of the muscles in the gut-wall. Invagination is a disease of childhood, and especially is it a disease of those patients whose cranial brain is defective and has lost effective control over the abdominal brain (the semilunar ganglia). Twenty-five per cent. of invaginations occur in children under one year, and fifty per cent. occur in children under ten years. We may expect invagination when the abdominal brain or its conducting cords are injured or defective.

The ideal of a nervous system is: 1, a ganglion; 2, a conducting cord, and 3, a periphery. An injury or defect of any one of the above three paves the way for invagination. Invagination is liable to follow any operation which has required complete severing of the gut, as that injures the conducting cord and periphery of the abdominal brain or semilunar ganglion. Hence we must learn to avoid invagination in circular enterorrhaphy, Jobert's operation with all its modifications, the stove pipe joint operation which I have introduced and performed many times successfully, and, in short, in all operations where the gut is entirely cut into two parts. For some three years I have talked and written about invagination subsequent to intestinal operations, but I have never heard or seen a single comment on it. It is apparently as if it had never happened or been published. But I think I lost about eight dogs in two hundred and twenty-five from this kind of invagination. It happens in this wise: A bowel is completely severed and its ends are invaginated for, say one quarter of an inch to one inch, and then it is fixed in this position by four to six Lembert sutures. A graft is applied and fixed in location by a few sutures. In a few days or a few weeks this invaginated bowel simply continues to invaginate until it interferes partially or completely with the fecal current.

Invagination subsequent to operation is liable to follow in circular enterorrhaphy, in Jobert's operation, and, last but least, in lateral anastomosis by plates. In this article I present the cut of a specimen taken from a dog which died ten weeks after an operation for lateral anastomosis. The gut was completely severed and invaginated one-quarter of an inch, and sutured in position by four Lembert sutures. The lateral anastomosis was performed with my segmented rubber-plates, and graft applied by fixation sutures.

The dog died from pure marasmus in ten weeks, caused by the distal cut end of the bowel continuing to invaginate until the invaginated segment interfered with the fecal current fatally.

The proximal end of the gut was much thickened and dilated. Its pathology showed a chronic process. The dog was a mere skeleton, a dime museum cage of bones. He had spells of vomiting, and many days at a time he refused to eat.

The autopsy showed all else normal. The invaginated segment was composed of the distal end above the anastomosis. The purpose of the operation of lateral anastomosis on this dog was to prove that a bimucous fistula will gradually close to a dangerous degree. I was going to keep the dog a year, but his premature death confirmed and proved what I had observed for three years in experimental work, viz., that invagination subsequent to complete severing of the gut will occur in about four per cent. of cases.

The first question to ask is, Is a dog's gut and a man's gut comparable as to operation? If a man's gut is like a dog's gut, then operative proceedings will be alike for both. So far as I can judge, a dog's gut is distinctly and properly comparable in operative procedures to a man's gut, therefore, operations performed on either will be accompanied by similar results. I have examined carefully a great many digestive tracts of both man and dog, and I know that the muscular wall of a dog's gut is a little thicker than a man's gut-wall. Also, there is a thicker aponeurosis or fibrous sheath in a dog's gut wall than there is in a man's gut wall. But I do not think that there will be any material different results in operative procedures.

The second question to ask is, How are we to avoid invagination subsequent to operation on the gut?

After invagination had occurred subsequent to circular enterorrhaphy, I began to use a rubber band or ring, but that did not prevent subsequent invagination. The dogs died from the invagination just as much with a rubber ring or band as without them. I worked some six months on plans, and finally I began to use the rubber tube from four to eight inches long. This rubber tube, adapted to the size of the bowel, was stitched into the segment of the gut when the circular enterorrhaphy was per-

formed. The tube was made to project three quarters up into the proximal gut. The tube, by distinct methods of stitching, could be made to remain in the bowel from three to eight days, as desired. With this rubber tube I do not now remember to have had one death from invagination subsequent to operation until the case reported in this communication. Hence the rubber tube six to eight inches long, adapted to the size of the gut, is the most effective remedy against invagination of the bowel subsequent to intestinal operations. The tube must not fit the bowel too tightly, or it will produce gangrene. But in invagination following lateral anastomosis, as in the present case, more trials will bring light, no doubt. Of course I can very distinctly warn the intestinal operator that the less gut end he invaginates before fixing by sutures the better. I have had gut ends continue to invaginate about fifteen to twenty times in two hundred and twenty-five operations, but the invagination did not appear to do any harm. But the dogs were killed too early to speak of what final results would be. I now try to invaginate between one-eighth and one-fourth of an inch of gut.

Another view I have obtained from experience is, that the lateral anastomosis should be done as near the end of the closed gut as possible; for then the short muscles of the distal gut end will probably not be able to get sufficient start or purchase power to continue the invagination.

The final suggestion that I have to remedy the invagination subsequent to lateral anastomosis will, I think, be effective. It is to stitch the end of the distal gut to the side of the proximal bowel. This, I think, will effectually check any further invagination. It should be done with two lateral and one middle Lembert sutures. For fear that the end of the proximal bowel might take a capricious notion to invaginate, it should also be stitched to the distal bowel by three Lembert sutures. Something may be done to prevent invagination by various methods of shortening the mesentery by reefs and tucks. But in my experience the mesentery so elongates by slow stretching that it is not wholly reliable.

Venetian Building, 34 Washington Street, Chicago, Ill.

CASE OF TRAUMATIC IRIDO-CHOROIDITIS FROM CONTUSION OF THE EYEBALL, ENDING IN THE DEVELOPMENT OF INTRA-OCULAR GLIOMA.[1]

By CHARLES STEDMAN BULL, M.D.,

new york.

Maggie P——, aged three, was first seen on December 9, 1890, and the father gave the following history: On November 28th, while seated at the dinner-table, the child was struck a severe blow on the left eye by a large table-spoon in the hands of an older child. The convexity of the bowl of the spoon struck the eye. The child immediately cried out and complained bitterly of the pain. The eye was bathed with cold water by the mother, and after a while the child stopped crying and complained that she could not see. The lids remained swollen for nearly a week, and there was some discharge of a muco-purulent character. On December 9th, when I first saw the child, the swelling of the lids and the discharge had entirely ceased, but the eye was apparently sightless. There was a central infiltration of the cornea with loss of the epithelium; a dilated, discolored, and immovable iris, marked ciliary injection, and a slightly hazy vitreous. With the ophthalmoscope there was a distinct yellowish reflection from the nasal half of the fundus, which was most marked in the supero-nasal quadrant, and seemed to be due to an exudation with vessels running over it. The refraction of this part of the fundus was + D. 1. The child complained of no pain and the eye was not sensitive on pressure. The other eye was normal in every respect, and the child appeared healthy, and had always been so. The family history was very unsatisfactory, one child, an older brother, had died of pulmonary tuberculosis, and a maternal aunt had died of some form of brain disease.

On December 15th there were numerous hemorrhages found in the retina and vitreous, and the tension of the eye, which had been normal, perceptibly increased. From this time, however, all external signs of inflammation slowly subsided. The ciliary injection disappeared, the vitreous cleared up, there was no recurrence of the hemorrhages, and no pain.

On March 20, 1891, I discovered an extensive lobulated detachment of the retina outward, upward, and downward, with marked fluctuation of the detached retina. Over the rest of the fundus was a yellowish reflex with a few blood-vessels running over it, and resembling both an intra ocular neoplasm and a mass of exudation. From the history of the case and my continued observation of it, I was inclined to believe it to be a mass of exudation the result of a choroiditis and hyalitis. The tension still remained above the normal standard, and I therefore advised enucleation, but the parents declined it.

On May 4th I first noticed an apparent thinning of the sclera in the ciliary and equatorial regions, and as the tension was still increased I urged an enucleation, to which the parents would not consent. I saw the patient once a week till June 1st, and then did not see her again until October 30th. Up to June 1st there was no change in the appearance of health of the patient, but on October 30th there was a very decided change for the worse. The child was anæmic and emaciated, and scarcely ate any food except what was forced on her. Between June 1st and October 30th there had developed a very large ciliary and equatorial staphyloma, and the sclera had become so thinned that in the supero-nasal quadrant it had nearly perforated. There was almost no anterior chamber, the iris being dilated *ad maximum*, and closely applied to the cornea at its periphery. The lens was opaque and pushed forward almost against the cornea. The tension was + 2. The eyeball was freely movable in all directions, and there was no pain and no sensitiveness on pressure. I again urged an enucleation, and the parents consenting, the left eye was removed on November 2, 1891. The child immediately began to improve in appearance. Under the influence of iron, quinine, and plenty of food, she increased in flesh and weight, and this improvement continued until December 19th, when she began to complain of headache and nausea, and actually vomited several times. The orbit was carefully examined and nothing abnormal found.

On December 26th the left pre-auricular gland was found to be enlarged, as well as the gland at the angle of the jaw on the left side. One week later the submaxillary and upper cervical glands on the left side were found enlarged. There was still nothing discoverable in the orbit, and the other eye remained intact.

On January 11, 1892, she complained bitterly of severe frontal headache, sometimes screaming aloud from the pain.

On January 14th there was first noticed a probable return of the growth in the orbit, the tissue at one point being hard and infiltrated, and the lids being slightly swollen and sensitive. By February 5th, there was a very perceptible infiltration of the orbital tissue along the floor of the orbit, and a more decided enlargement of the glands on the left side, particularly of the submaxillary gland. The frontal headaches were now constant and very severe.

On February 12th the symptoms were all more marked, and for the first time the right eye was found to be involved, there being a small but distinct yellowish reflex in the infero-temporal quadrant of the fundus.

On February 19, 1892, the glandular enlargement on the left side of the neck had become enormous, so

[1] Read before the American Ophthalmological Society, July 20, 1892.

that the head was carried toward the right side, and there was considerable difficulty in opening the mouth. The left orbit was filled up by the new-growth nearly to the orbital margin, and the lower lid was pushed forward. In the right eye the iris was very much dilated, and very sluggish and discolored, and there was a large and distinctly elevated yellowish patch in the infero-temporal quadrant of the retina. There was no marked change in the appearance of the papilla, but the child was evidently nearly blind, there being faint quantitative perception of light. This was the last time I had an opportunity of examining the child, as she became stupid and gradually comatose, and died early in March, 1892. Most unfortunately, an autopsy was not permitted by the parents.

The eyeball which was enucleated was given to Dr. J. E. Weeks, the pathologist of the New York Eye Infirmary, who has been kind enough to make a careful examination of the specimen, and has sent us the following report: The eye measured 24 mm. in the vertical diameter, 24 mm. in the transverse diameter, and 32.5 mm. in its largest diameter through the apex of the staphyloma. The latter measured at its base 18.5 mm. by 10 mm. On opening the globe, the anterior chamber was found to be almost abolished, the lens being pushed forward by a large grayish mass which extended from the posterior part of the globe forward to and filling the staphyloma. At the equator the grayish mass was separated from the sclera by a collection of thin brown fluid.

Microscopical Examination.—The iris was atrophic and was firmly adherent to the cornea at its periphery. In the vicinity of the staphyloma it was entirely disorganized. The lens was pushed forward and decidedly shrunken, so that it did not fill its capsule. The ciliary body was much reduced in volume and decidedly flattened, and at the site of the staphyloma it was entirely destroyed.

The choroid was very much atrophied, and a few isolated groups of glioma-cells were found on its inner surface. Very little of the retina could be recognized. Anteriorly, but away from the vicinity of the staphyloma, it was atrophic, but traces of it were still present. Farther back it was infiltrated with small cells and was enormously thickened and soon lost in the central mass, its elements being entirely indistinguishable. In the optic nerve there was a small cell-infiltration of the nerve-bundles, and a collection of small cells in the sheath. It was difficult to determine whether these cells were merely leucocytes or something else. In the sclerotic, at the apex of the staphyloma, the connective-tissue bundles were separated from each other, the spaces being filled by the cells of the new-growth. In some places the cells extended almost to the surface. Wherever vessels or nerve-trunks passed through the sclerotic a small cell-infiltration was found. The cornea was almost normal. The central mass was composed of an aggregation of small cells with large nuclei and little protoplasm; very fine fibres, apparently off-shoots from the cells, passed in all directions. Vessels with very thin walls passed through the mass in all directions, and in some places were surrounded by quite wide lymph-spaces. The tissue is apparently that of glioma.

Camphoid.—Dr. Martindale (*Phar. Jour. and Tr.*, 1892) gives the name camphoïd to a 1 to 40 solution of pyroxyline in Rudini's solution of camphor in absolute alcohol, made by adding to camphor its own weight of absolute alcohol. This solution, when painted upon the skin, leaves, after evaporation, a thin pellicle or membrane-like covering, and the author thinks it may prove a good substitute for collodion, since washing does not cause its removal. The solution, furthermore, readily dissolves phenol, salicylic acid, resorcin, chrysarobin, and iodoform.

Salol in Cystitis.—Dr. E. M. Sympson has awakened to the knowledge that salol in doses of five grains is most efficacious in cystitis.

Clinical Department.

A CASE OF ACQUIRED COMPLETE ATRESIA OF THE CERVICAL CANAL, WITH MENSTRUAL RETENTION, RESULTING FROM SYPHILITIC ULCERS IN THE CANAL.

Operation by Professor Hennig, of Leipzig, with Complete Recovery.

By M. W. BARNUM, B.S., M.D.,

ASSISTANT SURGEON, UNITED STATES NAVY.

The following case, which on account of its rareness, is pathogenetically interesting, was given to me some time ago in Leipzig by Professor Hennig, for the purpose of publication.

Emma G——, servant girl, aged twenty-three. The patient was of middle height, dark, well-formed, and had the appearance of being strong and healthy. She did not remember at what age the menses had first appeared; but stated that the flow had always been regular and normal, and that she had never been pregnant. When she came to the clinic it was with the complaint that for several months she had not menstruated, and that she had intense pain in the lumbar and sacral regions, and also in the lower portion of the abdomen. These pains, according to her description, strongly resembled labor pains. Every four weeks her symptoms appeared with great intensity, and were accompanied by a feeling of tenseness and fulness across the abdomen. Of late, the pain had become so agonizing in character, that at times she lost control of herself, and could but roll over and over on the floor. Besides these symptoms she complained of pain in the stomach, nausea, and anorexia; she also complained of a spasm at the neck of the bladder, and a mucous discharge from the vagina.

In making a physical examination of the case, the inguinal glands were found to be greatly enlarged, but not painful. In the throat papulæ were discovered, and she finally confessed exposure to specific virus.

By an examination per vaginam the os uteri was found to be hard, the cervix elongated and pointed. With the speculum the external os was found to be pale, narrow, and had evidently a lining of cicatricial tissue. The cervical canal was only penetrable for three millimetres with the smallest silver sound. By means of the combined touch per rectum, one could feel the uterus round as a ball, and of about the size it should have had in the second month of pregnancy. The uterus was within the pelvis proper, and was readily movable in all directions. The consistency of the uterus, when tested with the apposed fingers, was tense and elastic. The ovaries were normal, and no abnormality of the Fallopian tubes was discoverable. The diagnosis was: Atresia of the cervical canal with hæmatometra, the atresia probably being of specific origin.

The patient was admitted to the Hospital of Professor Hennig, and an operation was performed on July 24, 1889. The bladder and rectum being emptied, chloroform was administered. When narcosis was complete a sharp-pointed sound was brought into the os, under guidance of the finger. Then controlling the instrument from the rectum, the uterus being fixed through the abdominal wall by the hands of an assistant, the sound was forced through the canal for three centimetres. The sound was then withdrawn, and Kuechenmeister's metrotome introduced and thrust through the wound, the opening being in this manner laterally enlarged. This instrument, devised by Dr. Kuechenmeister, is twenty centimetres in length, curved like a uterus sound, and bears a button on the end. The lower portion, just above the button, consists of a thin, oval, horizontal, double-edged blade, about two centimetres long and one centimetre wide. Through the opening thus widened escaped about ten grammes of thickened blood of tarry consistency, mingled with pus and clots of blood. The

evacuation of the uterine cavity was assisted by flushing with tepid water, through Bixby's two-way uterus cannula. A microscopical examination of the blood showed disintegrated corpuscles, crystals of hæmatine, and a number of round pus-cells. A laminaria tent was then introduced into the wound and a tampon of iodoform gauze into the vagina. The subsequent course was apyretic and in every way uncomplicated. Therefore, on the eighth day after the operation, a mercurial treatment by inunction was begun. This treatment was continued for three weeks, and at the same time sitz baths and full baths frequently given. The general condition of the patient was bettered, and the papulæ in the throat vanished. The next menses occurred without complication, and the discharge was free. The patient was thereupon allowed to leave the hospital.

Since that time up to the present, or at any rate about eight months ago, when I saw the patient last, she had menstruated regularly and with but little pain. The cure was complete.

In this case the atresia had quite evidently resulted from cicatricial contraction, following the proliferation of connective tissue incident to the adherence of the contiguous ulcerated mucous surfaces in the cervical canal.

United States Naval Hospital, Washington, D. C.,
April 28, 1892.

THREE CASES OF MALARIA IN CHILDREN TREATED SUCCESSFULLY BY METHYLENE BLUE.

By JOHN H. HUDDLESTON, A.M., M.D.,

ATTENDING PHYSICIAN TO THE MEDICAL DISPENSARY, GOUVERNEUR HOSPITAL; ASSISTANT IN CLINICAL MEDICINE, NEW YORK HOSPITAL.

July 7th, three sisters, aged respectively ten, seven, and five years, came to the Medical Dispensary of Gouverneur Hospital with this history: For about two weeks all had been suffering every second day with chills and fever. The chill, severe enough to cause general shaking and chattering of the teeth, began usually nearly at 9 A.M. and lasted about an hour; there followed a fever and then a cold sweat. Toward evening they recovered, and the next day they felt perfectly well. The day following the attack was repeated. The children were Russian Poles, and had reached this country with their father and mother about a week before the illness began. The mother was similarly ill three days, and then recovered untreated. The father remained well. The children had always been well before coming here.

Physical examination showed them to be fairly well-developed and nourished, but all somewhat pale; lungs and heart in each presented nothing abnormal. In the oldest the upper limit of the splenic dulness was found at the eighth rib in the anterior axillary line, but no tumor was palpable. In the younger children neither percussion nor palpation revealed any enlargement. This was on a day between the chills. The next morning at 8.30 I saw the children and found the youngest apparently convalescent from an attack which, by the mother's account, had lasted most of the night. The other children were well; all the temperatures were normal. At noon I found that both older children had had chills in the forenoon, and were then in the fever; the temperature of the oldest was 105.2° F., and of the second, 102.4° F. Cover-glass preparations of the blood from all three were made, and the plasmodium seen in that from the oldest. In the others nothing abnormal was noted. The same evening the administration of methylene blue was begun, one capsule containing a decigram being given to the oldest every three hours, to the next every four hours, and to the youngest every five hours. This was continued regularly for four days, except that the medicine was not given at night when the children were asleep. The temperature was taken at noon daily, and found normal regularly, except that on the second day the second child had a temperature of 100° F., with no other symptom. The urine, colored blue, was passed without difficulty, and in sufficient amount in every case. Examination of the sediment gave a negative result. All medicine was stopped after the fourth day; the blood was again examined and nothing abnormal noted. Since then there has been no relapse.

70 West Eleventh Street.

Progress of Medical Science.

First Sign of the Menopause.—Naphey says: "In the change of life the first sign is visible at the lower part of the neck, on a level with the lower two cervical vertebræ. There commences an accumulation of fat, which often grows to form two distinct prominences, and is an infallible index of the period of a woman's life."—*New York Medical Times.*

Abnormal Sweating.—Dr. Frazer-Nash reports (*The Lancet*, April 2, 1892) the case of a Hindu boy, upon whose skin a crystalline deposit formed, which suggested the idea that he had bathed in a saturated solution of some salt, which had, in drying, deposited its crystals. The latter were glistening and amorphous to the naked eye, and required some friction to remove. About the head the crystals were larger than elsewhere. After two or three months of tonic treatment the crystals ceased to appear. The author had seen a number of similar cases, always in natives, but had been unable to discover the cause or the nature of the crystals. The urine was usually normal, and no irritation of the skin appeared to be produced by the deposit.

Purgatives after Abdominal Operations.—Dr. Championnière, in a discussion before the Société de Chirurgie (*Gazette des Hôpitaux*, No. 22, 1892), says it is at times difficult to establish a precise diagnosis between intestinal obstructions of various causes and true strangulation. In such case the administration of a purgative is an heroic measure to fix the diagnosis, and one offering no danger. He regards it as good practice to purge all patients as soon as possible after laparotomy. He admits that the rule may have its exceptions, but as a general thing this practice has given excellent results. Lawson Tait expressly recommends purgation each time the temperature goes up. Others as well as Championnière have adopted this method and have been satisfied with the results. It is admitted that where intestinal ulceration may predispose to perforation under the influence of a purgative, the latter should be withheld. He believes fully, in spite of the contrary opinion of Dr. Routier, that patients may die of intestinal paresis, and has observed cases which leave no doubt in his mind regarding it. Almost unanimity of opinion regarding the value of purgatives prevailed among the laparotomists who entered into the discussion, and most of them agreed that their early administration was advisable. The only difference between Dr. Championnière and his colleagues being that he purges as early as the day after operation, and many of them prefer to wait a few days.

Labyrinthine Deafness Treated by Pilocarpine.—During the last few years a number of papers have been published detailing cases of deafness treated by the use of pilocarpine. In the *British Medical Journal* for April 2, 1892, is a paper by Field, of London, in which he details the results of his use of the drug. His method of administration is to inject into the back of the arms a solution of nitrate of pilocarpine, of a strength equal to one-third grain to ten minims. The dose at first is one-twelfth grain, gradually increased to one sixth, and, if this is well borne, to one-fourth grain. Diaphoresis and salivation rapidly manifest themselves, and it is well to give a little ammonia in order to prevent the depression consequent upon the action of the drug. The patient is then made to lie on a sofa, and is well covered with rugs, the head

being enveloped in a shawl. These wraps are very carefully removed by degrees, in order to prevent catching cold. Untoward symptoms are not to be feared if small doses are used at first. The author is very positive that pilocarpine only does good to a certain set of cases, and gives the following rules for determining its indications: 1. The case must first be carefully diagnosticated as actually one suitable for treatment with the drug. Labyrinthine deafness, it must be remembered, is not a disease of common occurrence. 2. The larger number of the patients that hear better in a noise (when in a train or omnibus, for example) do not derive much, if any, benefit from pilocarpine, if used independent of other remedies. 3. The best test of hearing is to employ a large tuning-fork with a wooden handle, acting as a sounding-piece, to put on the head. Some of the small tuning-forks commonly used are worthless to the aural surgeon. 4. Cases in which the tuning-fork on the forehead is heard indifferently, or scarcely at all, may be suitable for treatment with pilocarpine. 5. Patients with a syphilitic history are usually much relieved, and the possibility of hereditary syphilis in a given case must be borne in mind. 6. The very large number of patients that say they hear worse after a cold are mostly unsuitable cases. 7. Patients who say they can hear when they are spoken to very distinctly, or whose deafness began with a difficulty of discriminating sounds, or who cannot make out general conversation, and hear worse when tired, nervous, or feeling out of health, are more promising cases than the last mentioned. 8. In arriving at a diagnosis, the state of hearing, as tested by the watch and the condition of the drumhead, should be noted. 9. Some cases of marked aural vertigo derive benefit from pilocarpine. 10. If middle-ear disease is associated with mischief in the internal ear, the Eustachian catheter should be passed from time to time for the injection of vapors.—*Therapeutic Gazette*, June, 1892.

Surgery of Pott's Disease.—Dr. Chipault (*Rev. de Chir.*, No. 7, 1891) presents some new facts relating to the subjects of caries, Pott's disease, and Treve's operation for lumbar abscess. In a case of tubercular caries of the bodies of the three lower lumbar vertebræ, with extension on the left side compressing the roots of the sciatic nerve, and causing severe sciatica, in a boy of nine years, large fungous masses of tubercular tissue were found and curetted. A fortnight later the pain and lumbar contracture had completely disappeared. In three other cases of Pott's, with paraplegia, the author has practised a method of treating ante-medullary lesions by trephining, opening the spinal canal, and drainage through the canal. Two of the cases recovered, and one succumbed to pneumonia a month after operation. The author's conclusions are: 1. The operation, which is anatomically possible, requires skill, though injury to the meninges and spinal nerve-roots is easily avoided. Drainage and irrigation of the centres of disease through the vertebral canal do not occasion disturbances of the medulla, even transiently. 2. In treating tubercular foci directly results not only palliative but curative may be hoped for, and such as are impossible with methods hitherto employed.

Hydrastis Canadensis in Obstetrics.—Dr. Bossi thinks that in hydrastis canadensis we have a remedy which will have a hæmostatic action upon the uterus without exciting it to contract, and one which can be administered with impunity during pregnancy or labor. He considers the stage of dilatation as the most favorable for its administration. His conclusions are as follows: 1. There is no danger to either mother or child attendant upon the use of hydrastis canadensis. 2. Its action is hæmostatic, whether used as a prophylactic or for its immediate effect, and there is no ecbolic influence exerted upon the uterine muscle. 3. Its value as a therapeutic agent in obstetrics is superior to that of ergot, since it accomplishes the same results without exposing the patient to the same dangers. The fluid extract may be used: *a*. In the hemorrhages which occur during pregnancy and the puerperal state, in the amount of from one hundred to one hundred and fifty drops a day, in three divided doses. *b*. In hemorrhage, during labor, in about four doses of fifty drops each. *c*. As a prophylactic against *post-partum* hemorrhage, and in cases of hydramnios, uterine inertia, and excessive development of the fœtus, in profound anæmia, and where previous labors have shown that there exists a tendency to hemorrhage.—*The American Practitioner and News*, February 27, 1892.

Salicylate of Bismuth in Infantile Diarrhœas.—Mikhnevitch (*Med. Obozrenië*, No. 6, 1892), having tried the salicylate of bismuth in 50 cases of diarrhœa in infants under two years of age, reports that, of the number, only 2 died (a boy of eight months with pelvic suppuration consecutive to intractable colitis, and an infant of five months, born prematurely and exceedingly sick since its birth). The following formula is recommended:

℞. Bismuthi salicylici ..... gr. xxiv.
Gummi arabici ..... ʒ j.
Sacch. albi ..... ʒ jss.
Terendo adde aq. dest. ..... ℥ ij.
Fiat lac, tum adde aq. dest. ..... ℥ iv.

M. D.S. The bottle to be kept in cold water or ice, and to be shaken well before use. One or two teaspoonfuls to be given from three to six times daily.

Each teaspoonful of the mixture contains about one-half grain of the salicylate, which constitutes a normal dose (three or four times daily) for an infant of from six to eight months of age. In cases of offensive diarrhœa the administration should be preceded by a dose of castor oil.

The Treatment of Posterior Spinal Sclerosis by Extension.—Dr. Benedikt (*Wiener Medizin. Presse*, 1892, No. 1) reports the employment of extension of the vertebral column in a considerable number of cases of posterior spinal sclerosis, with great improvement in gait and station, and mitigation of the neuralgic pains. He employed a modification of a method originally described by Bonuzzi, in which no apparatus is required. The patient is made to lie supinely on a table, bed, or sofa, with the head and upper portion of the spinal column partially elevated, while the lower extremities are grasped at the ankles and carried upward over the body and brought down over the shoulders. In this way, it has been demonstrated, a considerable degree of extension of the spinal column is obtained. The method possesses manifest advantages over suspension.

The Dyspnœa of Advanced Bright's Disease.—Dr. Steell thinks that common dyspnœa of advanced stages of Bright's disease is due to heart failure, and is not toxæmic. He points to the benefit obtained in many such cases from the hypodermic injection of morphia, as inconsistent with the presence of toxæmia. He recommends digitalis, or when it fails, strophanthus, citrate of caffeine, nux vomica, or strychnia. In paroxysmal dyspnœa he says the nitrates are disappointing; he recommends morphia, enjoining caution in its use, and its combination with atropine.—*The Birmingham Medical Review*, June, 1892.

Epidermine is another new local application recommended as a vehicle for the various drugs used in skin diseases, etc. It was introduced by Dr. Rothziegel, of Vienna, and is composed of water, glycerine, and beeswax. It has the appearance of a semi fluid, milky mass, and dries in the air. With iodoform in ten to twenty per cent. strength, it has proven efficacious in burns, and with ichthyol in erysipelas and frost-bites, while with iodide of lead it has been found to act well in glandular inflammation and orchitis.—*Journ. des Mal. Cut.*, May, 1892.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 13, 1892.

PROGRESS OF THE CHOLERA.

THE reports from Russia show that the cholera is steadily working along toward the western frontier, despite the efforts of the Russian authorities to stay it. We noted last week, that it had appeared at Warsaw, and since that writing other towns in Poland have been attacked. All the nations of Western Europe are adopting extraordinary precautions to prevent the disease from passing the Russian frontier, but it is hardly probable that it can be kept back entirely when there is such a constant stream of emigration from the country. The Berlin authorities have had the emigrant station at Runleben, near Spandau placed under government medical supervision, and no emigrants from Russia will be permitted to leave the train at any other station. The Austro-Russian frontier is guarded by a military cordon, and the autumn manœuvres of the Galician army, which were to have taken place in the presence of the Emperor at Przemysl, near Lemberg, have been abandoned.

The presence of cholera at St. Petersburg is finally admitted by the officials, and a panic has seized upon the inhabitants of the city, many of the merchants have closed their shops, and all who are able to get away are fleeing to the German and French watering-places. In Moscow, also, the panic is increasing, notwithstanding, or possibly because of, the efforts of the authorities to repress the publication of new cases of the disease. The medical lectures at the Universities have been suspended until November 1st, the students having been sent off to the infected districts to assist in combating the disease. At Nijni-Novgorod the fair is practically closed, and the city is in charge of the military. The government is distributing boiled water for drinking to the poorer classes, and, in order to induce them to take it in place of the ordinary water, has adopted the novel plan of mixing red wine with it. It is reported that four of the cholera victims in this city were American tourists who were so foolish as to visit the fair despite the warnings of the Russian authorities. An incredible report comes from Yaroslav, on the Volga, to the effect that the hospital authorities had a drain constructed through which all the sewage from the hospital was emptied into the Volga immediately above the point whence was drawn the water supply for the city. The report stated further that the Governor interfered. Well he might! Very few of the cities of Russia are sewered, even Moscow being unprovided with any other means for the disposal of refuse than cesspools. The total number of deaths from cholera in Russia up to August 1st was nearly 25,000.

From Vienna comes the disquieting news of the occurrence of several cases of "cholerine." It is possible, of course, that these are really nothing more serious than cholera nostras, of which there are numerous cases every year in most of the larger European cities. But at this time the presence of this affection naturally excites alarm. It is to be hoped that the city authorities will not try to dissemble, but will declare without reserve the nature of the disease. The truth is sure to come out sooner or later, and any attempt to repress it is short-sighted and will be productive only of harm. In Paris, cases of "cholerine" are still reported, and at Argenteuil over one hundred deaths occurred within a week from what was called choleraic diarrhœa and typhoid fever.

The epidemic in Persia, which was supposed to be subsiding, has broken out with renewed violence, the cities of Astrabad and Teheran being specially afflicted. In the former city serious riots have occurred, the dealers in liquor being the chief sufferers. The conscience of the people was touched, for they believed that the scourge was sent by Allah as a punishment for their disregard of the Koran's prohibition of wine-drinking, so they looted the liquor shops and drank up all there was to be had, in order that the practice might be put an end to at once. In Arabia, it is said, the Province of Harrar has been almost depopulated in consequence of the cholera, whole villages being deserted by their few remaining inhabitants.

No cases have been reported at the time of writing among any of the immigrants arriving at this port. There is need of special vigilance at this time, and it is reassuring to see that the authorities are fully alive to the responsibility that rests upon them. We wish that they had more capable ships' surgeons to rely upon for the medical history of each voyage; but in spite of this there is no cause for alarm in this country, and even if a few cases should step in it is unlikely that any epidemic will follow.

MURDER AND SEXUAL PERVERSIONS.

THE case of Alice Mitchell, which has just been tried at Memphis, Tenn., is a painful illustration of sexual depravity and the result of bad educational influences. The young woman was afflicted with an affection which Science, with a big S, calls *psychopathia sexualis*, and pronounces the subject a victim of a perverted sexual instinct. The pervert in this case attached herself to a Sapphic friend whom she killed one day in a fit of jealous fury. On trial, the defence of insanity was made. The medical experts were, we believe, unanimous in pronouncing the case one of a primary degenerative insanity; and the jury brought in a verdict of insanity.

We do not wish to contradict the combined testimony of so many alienists with reputations evidently very high in Memphis. Technically, perhaps, the girl was best considered insane; but we cannot avoid believing that if this alleged lunatic had been treated for worms, leucorrhœa, constipation, or some other of the frequent mechanical excitants of unhealthy sexual desire, or if she had been taken in hand early by those in authority, and received a course of bread and water, and perhaps some strong

corporeal applications, she would not have become a Lesbian lover or a murderess.

There is no function easier to control or to corrupt than the sexual. While some sexual perverts are born so, the majority are not, but form their habits through gradual vicious indulgence. Nearly all are amenable to moral influences, that is to say, to rewards and punishments. The sexual pervert may be technically insane, but he or she is legally responsible and should be so held.

Alice Mitchell has escaped the penalty of her depravity and her crime. The story may not be without profit to parents, however. The passionate friendships of young girls may be innocent and charming, but they need the wise scrutiny of those who have charge of them.

Perverted sexuality quickly breeds a desire for more and more filthy indulgence. Of nothing can it be more truly said: *Facilis descensus Averni.*

LARGE FEES.

A Chicago physician has received $2,000 for his services in a case of intubation for diphtheritic laryngitis. The parties disputed the bill for six months, and at last put it in arbitration. The full charge was allowed and promptly paid.

A New York physician was not so fortunate. His bill was $2,500 for ten days' attendance on a case of typhoid fever in a Southern town. The matter was sent to a jury, who awarded the doctor $1,500.

These cases have both been somewhat *causes célèbres*, and have led to many satirical remarks about doctors' fees. There may be extortionate charges occasionally, but, take it as a whole, the physician is poorly paid for the work he does. He never accumulates riches, and is generally fortunate if he saves enough for his old age. Medical services are worth more than in former years, and should be better paid.

The Ideal Family Physician.—The Hon. Thomas F. Bayard recently addressed the class at one of the medical colleges in Baltimore, having for his theme "The Lawyer and the Doctor." It has been his fortune, he says, to be thrown in contact with not a few medical men who have been "as the salt of the earth" in their respective communities. A man who is already eminent by reason of his natural endowments may be said to double his talent by becoming a physician. "It has been my personal fortune," says Mr. Bayard, "to know such a man. It has been my privilege and delight to accompany him in visits where his only medicines were the personal presence and conversation of the man himself. He had shared and had lessened their anxieties; counselled the wayward; cheered the weak-hearted; had rejoiced with them that rejoiced, and wept with the weeping. And I have seen such a man so surrounded by an atmosphere of love and trust, holding as it were the heartstrings of a family in his hands, their guide, philosopher, and friend; and then I realized what a moral force in society the profession, properly comprehended and properly followed, was capable of exerting, and how relatively small a part of its usefulness was the administration of medicine."—*New York Medical Journal.*

News of the Week.

Death of the Inventor of the Hypodermic Syringe.—The ordinary hypodermic syringe is known in France as the *seringue de Pravaz*, the instrument having been invented by Dr. Pravaz, of Lyons. The death of this gentleman is announced in this week's journals. He was the director of an orthopedic establishment in the silk capital, and was well known as a *médecin orthopédiste.*

Yellow Fever.—The Brazilian steamers continue to arrive at this port with yellow fever aboard. A week ago the steamship Glengoil from Santos and Rio Janeiro, was detained at Quarantine for fumigation, having had the disease aboard. Two of the crew had been sick during the voyage and one had died.

Dr. Hanson, of Norway, is about to go to the Sandwich Islands to study leprosy at Molokai, the Honolulu Board of Health having, it is said, sent him an invitation to do so.

Dr. Anthony Ruppaner, of this city, died suddenly in Pittsburg, on Sunday, July 31st. He was a graduate of Harvard Medical School in 1857, and was sixty-five years of age at the time of his death. He had been called to Pittsburg in consultation, and died of heart disease at the patient's house.

The Mississippi Valley Medical Association will hold its eighteenth annual session at Cincinnati, on October 12, 13, and 14, 1892.

The Best Way.—A lady writes in the *Housekeeper's Weekly* upon "How I Raised my Baby without Medicine."

"**Archives Provinciales de Chirurgie**" is the name of a new surgical monthly journal published in Paris. It is under the editorial management of Dr. Marcel Baudouin, and has been founded by a number of young provincial surgeons, as an energetic "attempt at surgical decentralization" in France.

American Dermatological Association.—The sixteenth annual meeting will be held at the Pequot House, New London, Conn., September 13, 14, and 15, 1892. The following papers are announced. "Iodine and Carbolic Acid in the Treatment of Skin Diseases," by Dr. C. W. Cutler; "Additional Note on the Treatment of Erysipelas, Based upon a Second Series of Fifty Cases," by Dr. C. W. Allen; "A Suggestion for Operative Procedure on Erectile Nævi over Fontanelles, etc.," by Dr. S. Sherwell; "How Should Dermatology be Taught?" by Dr. G. H. Fox; "A Somewhat Unusual Case of Lupus Ulceration of the Nose," by Dr. H. W. Stelwagon; "Lupus Vulgaris Following Exposure to Tuberculous Sputa," by Dr. W. T. Corlett; "Notes on the Treatment of Lupus Erythematosus," by Dr. J. Zeisler; "Alopecia Prematura; its Most Frequent Cause," by Dr. G. T. Elliot; "Cases of Favus Contagion from the Lower Animals," by Dr. S. Sherwell; "Some Observations on the Growth of Achorion Schoenleinii in America," by Dr. L. Heitzmann; "Morphœa Atrophica," by Dr. R. W. Taylor; "Psorospermosis," by Dr. M. B. Hartzell; "Report of a Case of Adenoma Sebaceum, with Microscopic Drawings," by Dr. J. A. Fordyce; "Concomitance and Sequence in Skin Eruptions, and the Influence of One Der-

matosis upon Another," by Dr. C. W. Allen; "The Cicatrices of Syphilis," by Dr. J. N. Hyde; "An Unusual Case of Syphilis," by Dr. R. B. Morison; "An Exaggerated Case of Impetigo Contagiosa," by Dr. G. T. Elliot; "Notes on a Recent Visit to the Leper Hospital at Havana; Leprosy in Charleston, S. C.," by Dr. W. T. Corlett; "Notes on the Use of Thilanin," by Dr. G. H. Fox. The morning session of the second day will be devoted to a discussion of alopecia areata.

An Anti-Cancer League.—In March last Professor Verneuil suggested to his colleague, Professor Duplay, the idea of forming an association the *raison d'être* of which should be the elucidation of the real nature of carcinoma. The idea has now been acted upon, and a committee has been appointed to further the development of this deserving enterprise. The committee includes such well-known workers as Duplay, Trasbot (of the Veterinary School of Alfort), Metchnikoff (of the Pasteur Institute), Reclus, Ricard, and Brault, with M. Masson (the publisher) as treasurer. These gentlemen have just issued an address to the public disclosing therein the objects of the League, and asking for subscriptions in aid of researches. An appeal for collaboration is made to pathologists, clinicians, histologists, microbiologists, veterinary practitioners, and even geographical explorers. Congresses will be periodically held in order to discuss the progress made in bringing to light any information concerning cancer; a journal will be published as the organ of the League, and, when funds permit, prizes will be offered for any discovery bearing on the subject. We can only wish the enterprise success in its arduous mission.—*Lancet.*

Harvard Commencement.—At the Commencement at Harvard, on June 29th, 94 men received the degree of M.D. Of these, 68 were graduates of the three years' course and 26 of the four years' course, 13 received the degree *cum laude*, of whom 9 received also A.M.; 38 had previously the degree of A.B., and 3 some other degree.

The St. Louis Medical Society has refused to admit any more female physicians. It has one female member, who takes no part in the discussions. The members concerned in the rejection of female physicians claim that they should form a society of their own.

The Charlotte Medical Journal is the name of a new monthly, edited by Drs. E. C. Register and J. C. Montgomery. It is well printed and edited. The first number contains a good original article by Dr. Collins, of New York.

Dr. Benjamin W. McCready died at his home in this city on August 10th, aged seventy-nine years. He was born in New York, and was graduated in medicine from the College of Physicians and Surgeons in 1835, subsequently serving on the house staff of the New York Hospital. He was for many years Professor of Materia Medica and Therapeutics at the Bellevue Hospital Medical College. He retired from practice ten years ago, and for three years past has been in very feeble health, although his death at this time was not expected.

A Substance called "Divorcin" is said, in *Der Derenfreund*, to be an excellent remedy for hysterical attacks. Here is an opportunity for the paranomasiac.

Owing to a lack of funds, the Cincinnati Hospital has been compelled to close the venereal and ophthalmic wards.

Hypnotism and the British Medical Association.—Ten years ago the late Dr. Beard went before the British Medical Association and demonstrated some of the phenomena of hypnotism. He was insulted and practically mobbed by Drs. Crichton-Brown, Donkin, and others for his pains. At the recent meeting of the Association a committee, appointed for the purpose, report that they have satisfied themselves of the genuineness of the phenomena and of the therapeutic value of the method.

A Wise Board.—The Wisconsin State Board of Health has refused to recommend the adoption of certain works on "temperance," endorsed by the Woman's Christian Temperance Union, for use in the public schools. The Board adjudges the books to be unscientific and misleading.

The Illinois Board of Health has refused to recognize the diplomas of the German-American Homœopathic College, the German College of Medicine and Obstetrics, and the German Medical College, all of Chicago, and also the diplomas of the Toledo Medical College issued subsequent to the session of 1891.

A Death from Cocaine injection is reported to have occurred at Bellevue Hospital recently.

Professor Verneuil has, on the ground of advancing years, resigned the chair in the Paris Faculty of Medicine which he has so long occupied, with such advantage to the school and such honor to himself.

A Hospital for Consumptives is about to be erected in this city, at a cost of over $300,000. It is to be called the Seton Hospital, and will be under charge of the Catholic Order of Sisters of Charity.

The Complexities of Statistics.—*The Pacific Medical Journal* says: "It will be remembered that in the exceedingly interesting extracts from the San Francisco *Daily Report*, April 30th, to which we gave space in our last issue, appears the statement that during the past year Dr. G. W. Daywalt, 'the pioneer in diseases of mucous membranes,' lost only three out of 126 patients afflicted with diphtheria. Whether these 126 patients were residents of San Francisco or not, is not stated; but we are forced to the conclusion that 123 of them were residents of some other locality, perhaps the Farallones Islands, as of the twelve hundred cases of diphtheria reported to the Board of Health during the year 1891, we fail, after a most critical examination of the books, to find more than three reported by Dr. Daywalt. It is of course not to be supposed that he neglected to report 123 cases, for that would make him liable to a fine of $12,300 ($100 for each offence), besides exposing thousands of people to the danger of contagion."

The *Journal* seems to have placed the learned doctor in what is known nowadays surgically as an "orifice," from which only the technical skill of a Chicago orificialist can help him out.

Reviews and Notices of Books.

Transactions of the Medical and Chirurgical Faculty of Maryland. Ninety-third Annual Session, 1891.

The volume of four hundred pages contains about thirty papers on different topics with much information of interest to the members of the profession in Maryland.

Colorado State Medical Society. Transactions of the Twenty-first Annual Convention. 1891.

This volume contains the usual number of papers on various topics, some of them worthy of wider circulation than can be had when buried in a volume of Transactions.

The Human Figure: Its Beauties and Defects. By Ernst Brücke, Emeritus Professor of Physiology in the University of Vienna, etc., with a Preface by William Anderson, Professor of Anatomy, Royal Academy of Arts, London. 8vo, pp. 188. London: H. Grevel & Co. 1891. New York: B. Westermann & Co.

This book is written by one who requires little introduction to either the scientific or artistic world. The translator has brought to his task an excellent literary quality and a consuming enthusiasm. The book is a study of human anatomy from the standpoint of the artist and portrait-painter. Successive chapters treat of the head and neck, arm and hand, breast and shoulders, abdomen, back, pelvis and its relation to the trunk and thighs, and lastly, to the legs and feet. The different theories adduced are illustrated by references to the various masterpieces of ancient art, and thus the text is appreciated from its practical side. The book is one of great interest alike to artists and physicians.

The Mütter Lectures on Surgical Pathology for 1890–91. By Roswell Park, M.D., Professor of Surgery, University of Buffalo; Surgeon to the Buffalo General Hospital, etc. 8vo, pp. 293. St. Louis: J. H. Chambers & Co. 1892.

These lectures were published successively in the *Annals of Surgery* as they were delivered, and are here brought together in an attractive volume. They strengthen the argument in favor of the establishment of endowed lectureships on special topics. From this source has come during the last ten years, both here and abroad, no small part of our best and most trustworthy scientific knowledge. Of course, in a volume of this sort one must draw largely on the work of others; but Dr. Park has infused into it no little of his own originality, and has put forth much that has never before appeared in English dress.

The first topic considered is the general one of predisposition to infection, with a consideration of the causes of inflammation. Next comes an interesting chapter on pyogenic organisms and a general discussion of their relations to inflammatory conditions. Special chapter headings are surgical fever, peritonitis, tetany, actinomycosis, tuberculosis, pneumonia, and erysipelas. The chapter on pneumonia alludes also to the various exanthemata and diphtheria, while that on erysipelas includes lymphangitis, erythema multiforme, syphilis, gonorrhœa, etc. The use of different sizes of type gives a systematic arrangement to the volume, for which the printer has provided an attractive dress.

Space forbids our discussing in detail the various doctrines set forth. Dr. Park follows largely the views of the modern German pathologists, while not unmindful of the good work done by some of the English toilers in this field. A careful reading will well acquaint one with our residual knowledge of the great subject with which the lectures deal. It will also point out the side-paths which lead to regions as yet unexplored. Not only for consultation, but also for a practical laboratory guide, will the volume be of service, and we congratulate the author on this addition to American medical literature.

System of Practical Therapeutics. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Assisted by Walter Chrystie, M.D., formerly Instructor in Physical Diagnosis in the University of Pennsylvania. Vol. ii. "Fevers," "Diseases of the Respiratory System, Circulatory System, and Hæmatopoietic System," "Diseases of the Digestive System." With illustrations. Pp. 1158. Philadelphia: Lea Brothers & Co. 1892.

The second volume of Professor Hare's large work makes an early and welcome appearance. The first volume won unqualified approval on its merits, and its successor maintains its high standard, and will win fresh laurels for the work. Its scheme is admirable. Instead of giving the therapeutic actions of a drug, it takes up the diseases singly and treats of its therapeutics exhaustively, giving not one plan of treatment, but all known methods that are of the least value. The writers are the best in the profession, and when the work is completed it will be the most valuable treatise on therapeutics in the English language. The task of compiling it is stupendous, but Dr. Hare, with the assistance of Dr. Chrystie, is doing admirable work. The volume in hand opens with one hundred and fifty pages on the treatment of syphilis, by Professor R. W. Taylor. He believes in mercurial treatment by the mouth, beginning medication with the appearance of secondary symptoms. In addition to elaborating this treatment, however, he goes into detail concerning the abortive treatment (in which, by the way, he does not believe), inunction method, fumigation, hypodermic, and bathing methods. The treatment of hereditary syphilis is also exhaustively given. Dr. J. Lewis Smith writes on scarlet fever, measles, rötheln, and varicella. The subjects could not be in better hands. Among other methods of dealing with the hyperpyrexia of these diseases, Dr. Smith discusses the much-talked-of German method of cold and tepid baths, and lays down most excellent indications for their use, with full details as to the method of giving them. The complications of the diseases, including those of the eyes and ears, are fully dealt with. Space will not permit going into detail on each chapter, but they are all uniformly good and deserving of nothing but praise. "Small-pox" is in the hands of William M. Welch, M.D.; "Typhoid Fever," Frederick P. Henry, A.M., M.D.; "Typhus Fever," Manuel Dominguez, M.D.; "Malarial Diseases and Dengue," George Dock, M.D.; "Yellow Fever," Jerome Cochran, M.D.; "Cerebro-spinal Fever," J. C. Wilson, M.D.; "Diseases of the Respiratory System" are exhaustively treated by Drs. Ralph W. Seiss, Charles E. Sajous, R. Chalmers Cameron, James T. Whittaker, M. Howard Fussell, Edwin E. Graham, and Rudolph Matas; "Diseases of the Circulatory System and Hæmatopoietic System" are written about by Drs. W. H. Thomson, T. Lauder Brunton, Frederick C. Shattuck, J. H. Musser, and Richard C. Norris; "Diseases of the Digestive System" by Drs. A. D. Blackader, D. D. Stewart, Frederick A. Packard, Edward Martin, Roswell Park, and Charles B. Kelsey. These names are, without exception, those of the most eminent men in their several lines of practice, and are a voucher in themselves of the excellence of the work.

The Chinese: Their Present and Future; Medical, Political, and Social. By Robert Coltman, Jr., M.D. Philadelphia and London: F. A. Davis 1891.

This book describes the experiences which the author encountered while travelling in China. It is plainly written, gives some neat illustrations, and is sufficient to give an excellent idea of domestic life and domestic institutions in China. It is also very instructive, and is good for "leisure time" reading for the busy medical practitioner.

Society Reports.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-eighth Annual Meeting, held at Fort Griswold House, New London, Conn., July 20 and 21, 1892.

Gunpowder Injury to the Eyes.—The first paper was that of Dr. Charles A. Oliver, of Philadelphia, entitled, "History of a Case of Gunpowder Injuries to both Corneæ, Irides, and Lenses, with subsequent Restoration of Vision to almost full Acuity."

The patient, a young man aged eighteen, July 4, 1891, received the powder contents of a blank cartridge squarely in the face from a distance of three feet, the gravest part of the injury being several penetrating wounds of both corneæ, with deposition of powder in both irides and lenses. When the patient was first seen by the writer, sixteen hours after the accident, there was found to be in the left cornea a rather peripheral wound, with corresponding tear in the iris, through which a powder grain could be seen sticking to the lens. Another deep wound extended almost through the cornea. The fundus was apparently normal. In the right eye there was a penetrating wound of the cornea with injury to the iris. The lens was swollen and rapidly becoming opaque. Four days later there was an outburst of secondary glaucoma. Eserine and cold compresses were then employed; the following day an iridectomy was made. The wound healed promptly, and atropine was resorted to on account of slight tenderness in the ciliary region. In the left eye there was continuous improvement. When the patient was discharged, September 4th, there was good perception of light in both eyes. Two weeks later a broad, round hole was made in the lower half of the capsule, securing vision of $\frac{5}{10}$ with proper correction. A free double discission of the left lens was also done, obtaining vision of $\frac{5}{10}$. Since the discharge of the patient (one year), the eyes have remained perfectly quiet, and the patient pursues his occupation of outside delivery agent in a large retail store.

Removal of Fragment of Steel from the Vitreous Chamber by means of the Electro-magnet, with Preservation of Nearly Normal Vision.—Dr. Samuel Theobald, of Baltimore, reported this case. The piece of steel, which was very small, had passed through the margin of the cornea and through the iris near its periphery, but fortunately missed the lens. It had been in the eye eleven days when the attempt was made to extract it, and had excited a dangerous degree of inflammation. Under antiseptic precautions a longitudinal incision, about four millimetres long, was made through the sclerotic and deeper coats of the eye, between the inferior and external recti muscles and back of the ciliary body. Through this the sterilized magnet point was introduced into the vitreous chamber, and the bit of steel was withdrawn. The after-treatment consisted in the application of a lotion of opium and boracic acid, and the instillation of atropia. The eye is now (three months since the removal of the foreign body) very nearly normal in appearance, and has vision $= \frac{20}{xxv} +$.

Foreign Body in the Retina.—Dr. F. Buller, of Montreal, Canada, reported the case of a young man, who had been struck in the left eye with a piece of metal six days before coming under observation. There was a penetrating wound of the cornea with perforation of the iris and zonula, but no opacity of the lens. A short distance below the papilla was seen a piece of metal lying in the retina. Rest and instillation of a two-grain solution of atropine was ordered. Twenty-six days after the injury, the eye felt well. Vision $= \frac{6}{xx}$. There were pronounced evidences of neuro-retinitis. The piece of metal was still quite distinct. Fourteen months later the eye was still giving no trouble. Vision $= \frac{6}{9}$. The foreign body had entirely disappeared from view, and it was thought that an attempt to extract it would probably have to be made under less favorable circumstances than if it had been made while the body was in sight.

Traumatic Irido-choroiditis.—Dr. Charles Stedman Bull reported a case of this nature (see p. 189).

Hyaline Bodies in the Nerve-head.—Dr. George E. de Schweinitz, of Philadelphia, Pa., described hyaline bodies in the nerve-head from the standpoint of microscopic examination, and reported a case in which he had observed the well-known appearances of the globular formations in the papilla during life, and afterward had the opportunity of making a thorough microscopic investigation. The patient was a male, aged forty five, who had been injured in the head some twenty years ago. The optic nerves were partially atrophic, and the globular masses on ophthalmoscopic examination appeared in a circle slightly within the apparent margin of the nerve-head, and were capped with shining particles which glistened like cholesterine crystals. At the post-mortem examination the following lesions were found: 1. Compound hyaline bodies in the nerve head, situated in their seat of predilection within the tissue of the papilla, anterior to the lamina cribrosa. 2. Atrophy of the optic nerve, which may or may not have antedated the formation of the hyaline bodies, but which evidently was not caused by them. 3. Thickening of the coats of the arterioles in the optic nerve below the lamina, and in the central artery in the neighborhood of the compound hyaline bodies; a change in the adventitious coat of the vessel suggesting hyaline degeneration, but proved by differential stains to be composed of a different material from these bodies. It was held that they have nothing in common with the choroidal excrescences, but are the expression of a pathological process confined to a small portion of the optic nerve.

Etiology of Glaucoma.—Dr. S. O. Richey, of Washington, D. C., read a paper in which he argued that the prime etiological factor of glaucoma is constitutional. He traced the relation of glaucoma to the uric acid diathesis, and said that many manifestations of rheumatic gout are associated with chronic glaucoma, viz., enlarged or distorted joints, a peculiar senile pallor, or muddiness of the skin, periods of mental depression, and other symptoms attributable only to changes in the nervous system. The origin of chronic glaucoma was thought to be the absorption of toxic substances from the intestinal tract, the results of indigestion, and for which reason he claimed that operation in chronic glaucoma was unreliable.

Acute inflammatory glaucoma is a paroxysmal expression of the same condition upon which the chronic affection depends, and local irritation or trauma excites an attack of glaucoma only in the presence of the dyscrasia. Operation saves the eye during a paroxysm, but serves little purpose in chronic glaucoma, even when it does not, by irritation, precipitate a paroxysm. The speaker believed that by correcting and controlling individual habits, especially in the character and amount of food taken, more could be done to preserve vision than by operation; that there might be a possibility of aborting chronic glaucoma if the tendency to it was recognized at an early stage.

The Full Correction of Myopia.—Dr. Edward Jackson, of Philadelphia, Pa., reported the results of such correction in twenty-nine cases of patients under observation from three to ten years. In but three was there any notable increase in the degree of myopia, and these were hard students between the ages of twelve and twenty-one years, and under the full correction they had subsequently become stationary. It was hoped that the reporting of such results would do away with any timidity about ordering the proper concave glasses for constant use. The contra-indications were presbyopia and an exceptional inability to use such lenses for near work, similar to the inability of some emmetropics to do much near work without convex lenses; lowered acuteness of vision, so that the perfect retinal images were not appreciated; ha-

bituation to large blurred images that made sharper images unpleasant in old myopes; and divergent squint established to secure more perfect monocular vision. The temporary inconvenience or pain experienced on first using strong lenses should not be regarded as a contra-indication.

Dr. George C. Harlan, of Philadelphia, Pa., reported twelve cases in which full and constant correction of myopia, of degrees varying from four to sixteen diopters, had been worn for periods of from five to seventeen years. The ages of the patients varied from twelve to twenty-five years. In some the fundus was normal, in some there were moderate myopic crescents, and in others there were extensive choroidal changes. There was not the slightest loss in the acuteness of vision in any case. In eight, the myopia was stationary. In three there was a slight increase in myopia, but in one only was there a considerable increase. The speaker considered excessive convergence without accommodation the most important factor in progressive myopia, and he believed that restoration, so far as practicable, of the normal relation of these two functions was the most valuable therapeutic measure.

The General Form of the Human Cornea, and its Relation to the Refraction of the Eye and Visual Acuteness.—Dr. Swan M. Burnett, of Washington, presented a table showing the measurements he had made with Javal's ophthalmometer, of the cornea of forty-one eyes. These measurements demonstrated the fact that the cornea gradually diminishes in curvature from the visual axis toward the periphery, this diminution being much greater to the nasal side in both emmetropia and ametropia. The difference in the vertical meridian is less than that to the nasal side, but on the average greater than that to the temporal side. The practical inference from these measurements was that the place of election in an iridectomy is the temporal side of the cornea.

Some Incidental Phenomena of the Shadow Test.—Dr. Burnett also read a paper with this title. He believed the shadow test to be, for the generality of cases, a means of testing refraction reliable to within 0.5 D. or 0.75 D. He had examined a certain number of cases, however, in which the findings of skiascopy and by the test-glasses did not coincide. There was in these cases a play of shadows within the illuminated area, moving across the pupillary space, very similar to what is observed in conical cornea. He had not found the corneæ to be more irregular than in eyes which are normal and present no such internal shadows.

The phenomenon was due to some interference in the regular refraction of the light in its outward passage from the fundus, and must be found in the corneal substance (not sufficient to produce a discoverable opacity), in the lens surface, or the lens substance. Of the exact nature of this irregularity we are still ignorant.

The Law of Symmetry of Our Eyes as Manifested in the Direction of their Meridian; its Rules and its Exceptions.—Dr. Herman Knapp, of New York, read a paper with this title. There is a double symmetry in the human visual apparatus: 1, Each eye can be split by a horizontal section into a superior and an inferior half; 2, one eye as a whole is symmetrical to its fellow with regard to the median line of the body. Dr. Knapp discussed only the latter kind, and confined himself to the direction of the principal meridians in one eye compared with that of its fellow. He based his conclusions on the examination of 1,000 successive cases of astigmatism for whom he had prescribed glasses, and who had worn them with more or less satisfaction. The result was as follows: The meridian of strongest refraction (shortest radius of curvature) was:

A. Symmetrically placed in both eyes in eighty-four per cent., viz.: 1. Vertical in both eyes, 60.5 per cent. 2. Horizontal in both eyes, eleven per cent. 3. Diagonal, 45°, in both eyes, 4.3 per cent.; *i.e.*, *a*, upper end of both on nasal side, 2.7 per cent; *b*, upper end of both on temporal side, 1.6 per cent. 4. Intermediate, *i.e.*, between vertical and horizontal, omitting the diagonal direction, 8.2 per cent.; *a*, upper end of both on nasal side, 4.9 per cent.; *b*, upper end of both on temporal side, 3.3 per cent.

B. Unsymmetrically placed in both eyes, sixteen per cent.: 1. Strongest meridians intermediate; *a*, both nasally deflected (upper end on nasal side), 1.8 per cent.; *b*, both temporally deflected, 2.1 per cent. 2. Stronger meridian vertical in one, horizontal in the other eye, 1.3 per cent. 3. Strongest meridian vertical in one eye; *a*, nasally deflected in the other, 3.3 per cent.; *b*, temporally deflected in the other, 3.9 per cent. 4. Strongest meridian horizontal in one eye; *a*, nasally deflected in the other, 1.2 per cent.; *b*, horizontally deflected in the other, 1.6 per cent. 5. Strongest meridian nasally deflected in one eye, temporally in the other, 0.8 per cent.

The above retrospect shows a high degree of symmetry in one pair of eyes, viz., eighty-four per cent. The dominating direction is the vertical, sixty per cent.; next comes the horizontal with eleven per cent.; then the diagonal with 4.3 per cent.

If both meridians are vertical they are geometrically parallel, but they remain symmetrical just as if both were horizontal. Parallel direction in the intermediate position, for instance, 35° of temporal deflection in one eye, and 35° of nasal deflection in the other, occurs but very rarely. There was no instance of it in this whole series.

The symmetry of our eyes may give us many hints in the selection of cylindrical glasses. As symmetry is the rule, we should try to approach this rule also in the sixteen per cent. of exceptional cases, as near as this is compatible with a good correction of the visual acuteness. In conclusion, Dr. Knapp recommended that in our prescriptions of glasses the complete or incomplete symmetry should be at once apparent, saying, for instance, so and so many degrees of nasal deflection, viz., 10°, instead of 80° O. S. and 100° O. D. Furthermore, he proposed a classification of the varieties of astigmatism based on the direction of the strongest meridian, viz., vertical, horizontal, and intermediate or oblique astigmatism, where a deflection of 45° may be called diagonal. The oblique variety has to be subdivided into nasally oblique (simply nasal), and temporally oblique (simply temporal).

Dr. George C. Harlan, of Philadelphia, read a paper giving statistics of direction of the principal meridians of the eye, the results obtained being very similar to those presented by Dr. Knapp.

The Clinical Value of Repeated Careful Correction of Manifest Refractive Error in Plastic Iritis.—Dr. Charles A. Oliver, of Philadelphia, read a paper with this title, based upon a careful study of forty suitable cases, extending over a period of five years. The plan of study was not limited to the ordinary subjective method of lens testing only, but was accomplished by some of the more certain of the various objective plans, such as retinoscopy, opthalmoscopy (both by the direct and the indirect methods), the fundus image test, and lastly by ophthalmometry as a method of control; Thomson's ametrometer and the chromatic aberration test being used at times. As a result of these studies, Dr. Oliver concluded that the careful systematic estimation of the manifest error of refraction found during attacks of iritis was of great value in the rational and scientific treatment of this disease, not only offering itself as a means by which the general prognosis of the affection can be made more certain from time to time during its progress, but permitting itself to serve as a measure or guide, as it were, by which the attacks may be more properly and more understandingly treated, and their duration shortened by the judicious and intelligent use of appropriate drugs; thus giving better opportunity for lessening the chances of harmful and permanent after-changes to one of the most important; and yet one of the most susceptible, organs of the ocular apparatus.

Some Tenotomies of the Recti Muscles for Insufficiencies.—Dr. Oren D. Pomeroy, of New York, reported fourteen cases in which this operation had been performed, and stated that most of the cases of insufficiency that he had met had been relieved by correcting the ametropia. In performing the operation the conjunctiva is dissected as little as possible, and the tendon is divided at its insertion. The patient is then tested by prisms, and if more effect is desired more dissecting is done. It is difficult to tell by inspection whether or not all the tendon has been divided. A little over-effect is usually desired, and if considerable over-effect is obtained a suture corrects it.

Prominent Symptoms of Hyperphoria.—Dr. H. F. Hansell, of Philadelphia, presented a paper based on a study of thirteen cases of this condition. The symptoms given included only those positively traceable to the hyperphoria as demonstrated by their disappearance on the cure of the affection. In two of the cases the symptoms were purely local. Photophobia of moderate degree was present in five cases. Pain in the eyeballs, constant or induced by reading, was prominent in all cases.

Reflex Symptoms.—Six cases suffered with vertigo, and two had violent dyspepsia. In four cases the most prominent symptoms were excessive nervousness, irritability of temper, and at times mental confusion.

Intracranial Lesions with Defects in the Visual Fields.—Dr. Charles Stedman Bull, of New York, reported five cases of this nature in which the character of the lesion had been determined at the autopsy. The first case was that of a lady aged fifty years, who, four years before coming under observation, had received a severe and sudden mental shock, which caused a series of convulsions ending in a condition of profound nervous prostration. Then followed severe neuralgia, coming on every three weeks and lasting for more than a year. The first ocular symptom was night blindness in one eye, with progressive amblyopia. One year later the other eye became affected in the same way. Headaches then came on, boring in character and located at the vertex, but subsequently becoming continuous and confined to the occipital region. There was a large irregular central scotoma in the left eye for form and color, and a smaller scotoma in the right eye. The fundus of the right eye was but little affected, but in the left eye there was a neuro-retinitis in the stage of decline, and beginning atrophy of the optic nerve. The patient lived four years with steadily failing vision. During the last year she had repeated attacks of unilateral convulsions, became wildly delirious, and died in a violent general convulsion. The autopsy showed extensive patchy meningitis on the convexity of the left anterior lobe, some patches over the right anterior lobe, and one large patch over the right parietal lobe. All the arteries at the base of the brain were thickened and their lumen narrowed.

The second case was a young man aged twenty-four years, who had suffered from headaches, muscular twitchings in the upper extremities and face, and attacks of vertigo. The vision of both eyes became affected. There was concentric narrowing of the field of both eyes which steadily increased, and the vision slowly failed. The optic disks, which were at first hyperæmic, became pale and atrophied. The autopsy revealed a small-cell sarcoma involving the optic chiasm, both optic nerves, and the hypophysis.

The third case was a gentleman aged thirty seven years, who had suffered from severe headaches in the left parietal and occipital region, and from a loss of vision in the right half of each field coming on two months after the beginning of the headaches. Six weeks before coming under observation he suddenly lost the sense of smell. Examination showed a vision of $\frac{20}{50}$ in each eye and a bilateral right hemianopsia with concentric limitation of the remaining fields. In spite of treatment there was a steady failure of vision, and the patient finally died fourteen months after the first appearance of the headaches. At the autopsy a small-cell sarcoma was found in the cuneus, on the left side close to the median line.

The fourth case was a lady aged seventy-two years, who had suffered with headaches for more than a year. Six months before coming under observation she awoke with severe pain in the head and total blindness in the left eye. There was confusion of ideas, numbness of the right arm and leg, and thickness of speech. An examination showed slight ptosis of both upper lids, speech thick and slow, tongue pointing to the right side, vision $\frac{20}{40}$, slight lenticular opacities, and bilateral left hemianopsia. The ophthalmoscopic examination was negative. It was thought probable that the patient had a thrombosis and subsequent rupture of the middle cerebral artery on the left side. The lady lived for twenty months, during which time the vision failed but the fields remained unchanged. One morning she was found unconscious, and died three days later. The autopsy showed a patch of softening in the left anterior lobe and in a branch of the middle cerebral artery; running through it was an old plug which completely obliterated it. There was a recent rupture of a branch of the left middle cerebral artery, and a large clot of blood in the middle lobe of the brain close to the Sylvian fissure. All the arteries of the brain were diseased. At the base of the brain on the right side, overlying and pressing upon the right optic track, was a small-cell sarcoma the size of a hazel-nut, situated just in front of the corpus geniculatum laterale.

The fifth case was a gentleman aged thirty-five years, who had suffered for three years from severe headache beginning in the frontal region, but gradually extending all over the head, at first intermittent, but later constant. Occasional attacks of nausea and vertigo. Four years before he had received a violent blow on the left parietal region, which caused bleeding from the left ear and rapidly increasing deafness. Nine months before coming under observation, he began to see double. Six weeks after he came under observation, partial left hemianæsthesia appeared. There was paresis of both external recti muscles. Vision in the right eye was $\frac{20}{100}$, in the left eye $\frac{20}{50}$. There was marked papillitis with numerous hemorrhages. There was homonymous diplopia for all distances, irregular central scotoma for all colors, vertigo very marked with a tendency to rotate to the right side. Toward the end he became nearly blind, and died in profound coma. The autopsy revealed a glio-sarcoma in the right lobe of the cerebellum, close to the peduncle.

The Eye of the Negro.—Dr. Charles W. Kollock, of Charleston, S. C., read a paper based on a study of the eyes of negroes coming under his observation. Many of the individuals studied represented a very pure type of the race. Many of the eye affections are traceable to the effects of syphilis, and to the changed conditions in the life of the negro since the war. Ulcerative keratitis is quite common, but trachoma is exceedingly rare. Cataract is equally frequent in the negro and white. Glaucoma is also of equal frequency in the two races. Retinitis, optic neuritis, and choroiditis are not infrequent. The speaker had not seen retinitis pigmentosa in the negro. No case of embolism of the cerebral artery had been observed. Xerosis of the conjunctiva had been seen in one case, an adult. The negro seemed less likely to have orbital tumors. Two cases of abscess of the orbit had been seen in negro children.

Frequency of Posterior Capsular Opacities at the Place of Attachment of the Hyaloid Artery.—Dr. W. F. Mittendorf, of New York, presented a paper calling attention to the frequency of small, round lenticular opacities which the writer believed were either the remains of the fœtal hyaline artery, or marked the attachment of the artery to the posterior lens capsule. After observing two cases of remaining hyaline artery, the author studied every eye with a strong lens and the ophthalmoscope, and found that in 1,884 persons these opacities were observed in 44 cases, which is a little more than two per cent. of all per-

sons examined. They were observed more frequently in the right eye than in the left, and oftener in the male than in the female; not infrequently they were seen in both eyes of the same patient. They varied in size from a dot as small as the point of a pin, to that the size of a poppy seed, and frequently a magnifying power of a lens of five or six diopters was necessary to see them. The conclusions arrived at are as follows:

These opacities indicate the point of attachment of the fœtal hyaline artery to the posterior capsule of the lens, the nutrition of the capsule being sufficiently interfered with at the time of the absorption of the artery to lead to the cloudiness at this point.

The location of the spot on the capsule is almost invariably a little to the inner side of the posterior pole of the lens. The spots were usually well defined, and in only one out of forty cases were radiating lines, probably corresponding to branches of the hyaline artery, visible. In no case was there any connection of these spots with other opacities of the lens which were seen to exist at the same time. These spots are, therefore, non-progressive and do not lead to any impairment of vision, nor are they apt to lead to any refraction or other changes of the eyeball. It is only in very exceptional cases that they produce subjective symptoms, patient usually being unaware of their existence.

Their occurrence is by no means rare and, as they are congenital, they are found equally often in old and young people. The fact that they appeared to be oftener met with in the male than in the female the author considered accidental, as the number of eyes examined was hardly large enough to establish this point. Their greater frequency in the right eye was probably likewise accidental.

The Corneal Nerves.—Dr. Carl Koller, of New York, exhibited some "Preparations of the Nerves of the Cornea." Erlich's method of injecting a saturated solution of methylene blue into the vessels of a recently killed animal, colors the nerves of the cornea in a beautiful manner, but has the disadvantage of being only temporary, and does not permit of the making of preparations. The speaker had for some time been experimenting with the object of making the staining permanent, but as his method was not yet perfect, it was not described.

Scleral Puncture in Detachment of the Retina.—Dr. T. Y. Sutphen, of Newark, N. J., described the results obtained in two cases, the first successful in restoring useful vision, the second resulting in slight improvement.

In both cases the operation was made under cocaine, and with antiseptic care. The puncture was made with a narrow Graefe knife near the equator of the globe, between the insertion of the external and inferior recti muscles. With the globe well rotated upward and inward, the puncture was made directly through the conjunctiva, while the return of the globe to its normal position really converted the opening in the sclerotic to a subconjunctival opening.

Orbital Cellulitis.—Dr. E. E. Holt, of Portland, Me., reported a case of this disease, the inflammation spreading to the temporal region, thence to the neck, interfering with deglutition, and finally extending to the brain and producing death. A brief report of four similar cases was also given.

Inflammation of Tenon's Capsule in Mercurial Poisoning.—Dr. Charles J. Kipp, of Newark, N. J., reported a case of recurrent bilateral inflammation of the capsule of Tenon, in connection with mercurial poisoning. The first attack resulted from an injury, but the attacks continued to recur. The patient was employed in an incandescent electric lamp manufactory and had become poisoned from the mercury used in his work. The recurrences continued until he gave up this work, and since leaving it (a year and a half) he has had no attack.

Pulsating Exophthalmos.—Dr. R. A. Reeve, of Toronto, Canada, reported a case in which pulsating exophthalmos had followed trauma. It was thought that there was a lesion of the internal carotid, allowing the blood to enter the cavernous sinus. Pressure on the carotid proved of no avail. A year ago the right common carotid was tied, pulsation and bruit ceased for a few hours, and then returned. Some months later, as it was found that compression of the left common carotid stopped the pulsation and bruit, this vessel was tied, but the pulsation still persisted. There is pulsation in the right carotid above the seat of ligation. Pressure upon the right external carotid stops the pulsation and bruit absolutely.

Sub-conjunctival Application of Cocaine.—Dr. Carl Koller, of New York, read a paper in which he advocated the injection of cocaine beneath the conjunctiva in order to insure anæsthesia of the deeper tissues.

Election of Officers.—*President*, Dr. Hasket Derby, of Boston; *Vice President*, Dr. George C. Harlan, of Philadelphia; *Corresponding Secretary*, Dr. J. S. Prout, of Brooklyn; *Recording Secretary*, Dr. Samuel B. St. John, of Hartford; *Delegate to the Executive Committee, Congress of American Physicians and Surgeons*, Dr. John Green, of St. Louis; *Alternate*, Dr. D. B. St. John Roosa, of New York.

The next meeting will be held at New London, Conn., on the third Wednesday of July, 1893.

Correspondence.

THE HEALTH RESORTS OF THE RIVIERA.

(Continued from p. 112.)

VIII.—San Remo.

(From our Special Commissioner.)

GENERAL FEATURES OF SAN REMO—THE OLD TOWN—SOME HISTORICAL REMINISCENCES AND MODERN AMBITION—A GERMAN WINTER COLONY—THE OCEAN ROUTE BY WAY OF GENOA—A LOVELY SITUATION AND PROTECTION FROM THE WORST WINDS—THE AMPHITHEATRE OF HILLS—METEOROLOGICAL OBSERVATIONS—PREVAILING DISEASES—THE NEW CREMATORY—A PUBLIC DISINFECTORY.

> " . . . i monti Ligustici e Riviera,
> Che con aranci e sempre verdi mirti,
> Quasi avendo perpetua primavera,
> Sparge per l'aria i bene olenti spiriti."—L. Ariosto.

San Remo is the largest, the best, and in all respects, the most important winter station on the Italian Riviera. It has certain distinctive features which, being mainly of a favorable character, entitle the place to a high rank among climatic health resorts. Its natural advantages, *i.e.*, situation, protection from winds, etc., give it a winter climate fully as mild and equable as that of Mentone. In addition thereto this little Italian town has been fairly well piloted of late years as regards the introduction of a number of substantial improvements. Thus, since the new aqueduct has been completed, no better drinking-water is found in all Italy than at this place. New streets have also been constructed, old ones have been repaved, cosey villas have been erected, and well-equipped modern stores have sprung up. Cafés, restaurants, a theatre, spacious hotels with attractive gardens, all point to the flourishing condition of this city. Then, again, it speaks well for the common sense of the community that no attempt has been made to create a sudden boom, but that the people have been content to promote the healthful, steady growth of their town, which is so largely dependent on the continued good will of the foreign element. I was informed that of the hundred villas on the rent list not one was left unoccupied this season. At Nice and Cannes dozens of cottages have remained empty for several years past.

At present, under the powerful impulse of a new municipal administration, at the head of which stands the energetic Syndic (mayor) Signor Alessandro Escoffier, serious attention is being given to the introduction of a system of needful sanitary reforms which, if intelligently carried out, will make San Remo one of the healthiest, as it is now one of the most popular winter resorts on the north shore of the Mediterranean.

The town is essentially Italian, but the old San Remo of years ago has almost ceased to exist, except upon the hill, where the ancient houses are still huddled together in the gloomy but picturesque fashion common to all the Ligurian coast towns. One entire section of this mediæval city lies in ugly ruins, the earthquakes of 1887 having been severely felt here. The Mayor tells me that this ruined portion of the city is not to be rebuilt, but the space formerly occupied by rickety houses is to be utilized for a new park, as soon as the disfiguring rubbish of collapsed dwellings and churches will have been carted away. As the view from up there is remarkably fine, the new park will prove to be an attractive innovation.

In my rambles through the quaint old town I was struck by the exceptional cleanliness of the steep, narrow, winding labyrinth of flights of steps, dark alleys, and ancient brick-paved streets. It is a strange sight, this aged nucleus of a modern health resort. Overhead numerous arches connect house to house. Indeed some alleged streets seem more like vaulted cellars, where no straggling ray of happy sunshine ever penetrates, than like the common thoroughfares of human habitations. Yet, so far from reeking with filth, most of these dark and dismal alleys formed, by their "washed" appearance, a marked contrast to what I have seen in the cramped old native quarters of almost all other Riviera towns. Not that disagreeable smells did not sometimes remind me that there was room for further improvement, not that the habits of the native San Remese are above reproach, but official vigilance has here really resulted in establishing a state of affairs which, if the stringent new laws of Italy were always enforced, would leave little to be desired in the matter of public hygiene, and would soon result in a marked decrease of mortality from preventable diseases. Perhaps the San Remese are not entitled to all the credit for this state of affairs, for, quite apart from their good will, the very steepness of the streets gives the rain every opportunity to wash away all nuisances.

Old San Remo is built on a steep declivity, the idea of protection from pirates and corsairs having prompted the choice of site in all these ancient coast towns. Indeed, judging from the pipes for molten lead still seen over some gateways, from the ancient walls, with eye-loops once used for arrows, and from the brackets for the feet of fighting archers, many a fierce struggle must have occurred in the olden days, when the town was a formidable fortress protecting a thriving port. On the flanks of the city hill and along its fan-shaped spreading base, the new strangers' quarters are found. They look bright and cheerful, with their numerous little shops, large and small hotels, and an occasional old palazzo interspersed between pretty villas. There are a few wide streets now, notably the Via Vittorio Emanuele, Via Romana, and several Corsos, which, in spite of frequent clouds of dust, would do credit to much larger towns.

To the artist's eye the tortuous streets and blind alleys of the old town, which claims an antiquity of over two thousand years, will look invitingly sketchy at innumerable points. There are elaborately carved doorways of rare design, in which worm-eaten doors still loosely hang ajar, allowing you to peer into the forbidding darkness of crowded but happy homes. There are crumbling little shrines, mostly dedicated to the Santa Madonna, and bright in all this gloom with various votive offerings, telling their touching tales of simple-minded trust and piety. There is the ugly old cathedral of San Siro, with its mixed colors and more mixed architectural style. There is the sanctuary of the Madonna della Costa, crowning the summit of the old city hill, with its two cupolas gleaming white above the sea of many-tinted but always sombre houses. There are little vine-clad balconies perched up like birds' nests against upper stories of high tenements, clinging vine-stems carefully protected by sheaths of masonry rising from the street, and balconies getting at least a modicum of sunshine. And everywhere the odd arches span their mouldy shapes across the dingy streets, as if to link together for all eternity what the tooth of time is gnawing away to shapeless ruin.

The history of San Remo, like that of most of the coast towns of the Riviera, has been full of vicissitudes. It passed successively under different rulers and dynasties, being connected alternately with Ventimiglia and Genoa, being a fief in turn of the powerful family of the Dorias and of the Dukes of Savoy. French, Spaniards, and English have, at one period or another, taken possession of it. Sometimes it enjoyed a brief independence, and about a hundred years ago formed the capital of a Ligurian Republic, under the romantic name of the District of the Palms. Later it became a prefecture under Napoleon I., and finally passed under the government of Sardinia, being now incorporated with it in the kingdom of United Italy (Macmillan).

San Remo was at one time a flourishing seaport town with an extensive commerce. Even so late as the latter part of the eighteenth century, according to Elisée Reclus,[1] the San Remese still had some eighty vessels, which, being put in requisition by General Bonaparte for his Egyptian expedition of 1797, were taken by the English. This crushing disaster sounded the death-knell of the maritime supremacy of San Remo, then second only to that of Genoa on the Ligurian coast. And although the prosperity of San Remo has been almost completely re-established in other directions, it has not regained its former importance as a mercantile and trading centre.

The port is not accessible to larger craft, and it is doubtful if the contemplated harbor improvements will divert much business to the city. It would certainly not be an unmixed blessing if the present chief aim and concern of the community, namely, the attraction of winter residents from foreign lands, were to be diverted into the uncertain channels of new industrial enterprises. The turmoil of a shipping centre, like Genoa or Marseilles, is not conducive to the best interests of a tranquil health resort. San Remo, if it wishes to retain its prestige as a winter station for invalids, will have to give up its ambition to become again a city of commercial importance. I have alluded to this matter here, because I am well aware that there is a fighting section of the San Remese community who are opposed to all sanitary and similar reforms on the alleged patriotic ground that it is unnecessary to pander to the depraved taste of the foreigner, and that home interests are independent of the influx of strangers. If these minority kickers ever get control of the town San Remo as a sanitarium would surely rue the day.

For obvious political reasons, the Teuton prefers Italy to France. But ever since the lamented Emperor Frederick suffered heroic martyrdom at San Remo, the place has naturally attracted numerous Germans. The latter now organize veritable winter pilgrimages in annually increasing numbers to the Villa Zirio, once inhabited by their dying Crown Prince. It is not surprising, therefore, that the German character of the new winter town should be so plainly visible at every turn. The harsh Germanic guttural strangely offsets the soft sounds of the native Italian patois. On all public promenades, in many of the hotels, in shops, at public festivals, in the *Giardino Publico*, and everywhere where strangers mingle, the German contingent may be seen in full force. Several princes and princelings of leading Teuton tribes have made their southern headquarters here, while British aristocracy, as well as American plutocracy, is represented by a mere handful of permanents, and by only moderately numerous transients. On the other hand, mere "plain people," of Anglo-American origin, constitute a very fair proportion of the international winter colony. Doubtless, when San Remo becomes better known in our country it will be more largely patronized, especially as it has recently been made much more accessible by the new ocean route from New York to Genoa. Before the first-class passenger steamers of the North German Lloyd commenced run-

[1] Les Villes d'Hiver de la Méditerranée, p. 473. Paris: Hachette, 1864.

ning to the city of Columbus, Americans invariably visited the Riviera by way of Paris. And that meant getting down to Nice and Monte Carlo, or at most to Mentone, the entire Italian Riviera remaining unexplored territory. Should these boats continue to run, which is more than likely, the easiest way for American invalids to reach the Riviera in future will be per steamer to Genoa, and thence by rail along the Italian coast to France. Naturally, a large number of German physicians have established themselves at San Remo, and one of their number, Dr. Rieth, has just published a really useful work of the town, showing its indisputable merits as a health-resort.[1] Moreover, unlike most authors who have an axe to grind, this physician is not afraid to tell the truth, and boldly mentions some of the evident drawbacks of San Remo, as well as of the Riviera in general. From this work it appears that something like twenty-five per cent. of the winter visitors at San Remo are Germans. The following tabulated figures show this:

German and other Winter Visitors at San Remo.

Season.	Total Number of Visitors.	German Visitors.
1883–84	8,166	1,408
1884–85	3,755	602
1885–86	8,390	1,537
1886–87	5,523	1,083
1887–88	11,479	2,980
1888–89	17,567	4,356
1889–90	13,803	3,048

A German church, a German hospital, established in 1890 and called the "Kaiser Friedrich Krankenhaus," a German medical society, a German consul, German shops, drug-stores, boarding-houses, and hotels, all proclaim that the Teuton is more at home here than at any other resort on the Riviera. But I am not sure that, in spite of all this and the forced affiliation of the triple alliance, the lavish American or bargaining Briton is not just as warmly welcomed by a singularly obliging and undiscriminating people as any thirsty German ever is, even if he does part his hair in the middle all the way down to where his stiff neck is cemented on to his stiffer back. But since Russians are also found at San Remo, and as even Turks, Tartars, and Texans have occasionally made their winter home there, the international pretensions of the town may be said to be amply vindicated.

Like so many Riviera towns, San Remo is picturesquely situated on several slopes running down to a beautiful bay. The bay forms an inlet of the Gulf of Genoa, and where the new town stands it is shaped somewhat like an elongated S. The new mole which protects the shallow little harbor projects like a hook into the sea. The larger bay, extending beyond the city limits, stretches out for over four miles, with four minor indentations, in the shape of a graceful crescent. The eastern boundary is formed by a bold headland called Capo Verde (350 feet), while the western extremity is marked by the still higher headland of Capo Nero (800 feet). Hills and mountains rise from these promontories, protecting the town almost as effectually as Ospedaletti is sheltered. Monte Bignone towers up back of the city to the height of 4,270 feet. The hills are green with olive-trees, firs, pines, and large chestnut trees, so that the peculiar splendor imparted by a barren background of bare rock, as at Monte Carlo and Mentone, is not here seen, where a softer character is found in all the lovely landscape.

San Remo faces southwest. It lies about thirty-one miles in an easterly direction from Nice, sixteen miles from Mentone, and eighty-five miles west of Genoa.

The encircling hills which give protection to the town merit a somewhat more detailed description, which I borrow from Dr. Hassall: The first sheltering barrier is formed by a series of seven hills, intersected by valleys, through which flow small streams, or, as they are here termed, torrents. These valleys run from north to south and terminate in every case on the sides of the mountains in blind extremities. This first barrier of hills is succeeded by the range of mountains already referred to, (*i.e.*, those starting from the headlands of Capo Verde and Capo Nero). These are not thrown up into sharp, jagged peaks as at Mentone, but form an unbroken protecting chain and are mostly fir-clad. Behind this second range lies a third, the Alpes Maritimes, with an elevation of seven thousand and even eight thousand feet; these, however, are not visible from the town itself. Thus San Remo is enclosed and protected by a triple barrier of hills and mountains.

The biting north winds and the dreaded mistral are, therefore, never *severely* felt at San Remo. But to say that they are quite unknown there is a wilful misrepresentation. During my stay at San Remo, a period of several weeks, I was treated to dusty and violent east winds, which were almost as disagreeable as the true mistral. Nevertheless the general mildness of the winter climate at this place is amply shown by the luxuriant semi-tropical character of its vegetation. There is no doubt that the triple rampart of its encircling mountains gives it such substantial protection, because the hills are not here cleft by deep gorges and wide, open valleys, as is the case at most of the resorts on the Riviera.

Through the kindness of Dr. Hassall I am able to present to the readers of the Record reliable meteorological data concerning San Remo, based on eleven years' consecutive observations by that careful observer.

[1] San Remo, eine deutsche Winterkolonie. Von Dr. R. Koerner, neu bearbeitet von Dr. C. Rieth, K. Badearzt in Bertrich (Moselthal). Leipzig: Otto Wigand. 1892.

Table Showing the Winter Season Climate of San Remo.

	Season.[1]											
Temperature.	1879–80.	1880–81.	1881–82.	1882–83.	1883–84.	1884–85.	1885–86.	1886–87.	1887–88.	1888–89.	1889–90.	*Mean of 11 years.*

Mean minimum temperature on ground	.....	44.80	.... ..	39.53	42.82	38.44	40.77	38.60	.....	39 88	.....	40.69 Fahrenheit.
Times of freezing on ground	.....	3	0	20	4	29	13	34	12	26	12	15
Snow fell	1	0	0	2	0	0	0	0	0	0	3	
Sun and Sunshine [2]												
Mean sun-heat by naked thermometer		73	72	[illegible]8								*Mean of 9 years.*
Mean sun-heat in vacuo	119	.....	115	105.06	108	108	106	105.05	.....	105	.....	109 Fahrenheit.
Days on which the sun shone	166	160	167	160	171	163	162	166	.....	157	.....	164 days.
Mean sunshine per day, in hours and minutes	8.05	7.18	8.27	6.23	7.07	6.51	5.30	5.50	.....	6.12	.....	651 hours.
Total sunshine, in hours	1,331	1,177	1,412	1,171	1,290	1,242	999	1,255	.....	1,114	.....	1,221 total sunshine.
Rain, Rainfall, and Relative Humidity.												
Days of rain [3]	27	43	18	33	25	38	42	30	52	40	31	*Mean of 11 years.* 34 days of rain.
Hours of day rain	117	81	101	132	91	140	137	134	239	174	145	141 hours of day rain.
Total rainfall in inches	13.20	16.64	15.27	17.27	10.14	11.21	11.29	23.54	24.45	.....	17.90	16 total rainfall in inches
Mean relative humidity [4]	67.80	68.70	72.80	71.20	71.00	69.36	71.73	68.62	71.60	71.34	68.94	70.28 relative humidity.

[1] The season lasts from November 1st to April 30th. [2] In the first three years, the mean sun-heat in air and in vacuo is based on the days on which the sun actually shone, but in the following years it is spread over all the days of the season, even those on which the sun did not shine, hence a lower mean is shown in the eight later years. [3] Every day on which as little as the $^1/_{100}$ of an inch of rain fell is counted as a rainy day. [4] Based on three daily observations, at 9 A.M., 9 P.M., and 3 P.M.

No better idea can be formed of the salubrity of the San Remo climate than through a study of its vital statistics. The authorities placed at my disposal all their official records and in every way seconded my efforts to learn the truth. I cannot but express my admiration for the very complete and painfully accurate system now in vogue throughout Italy, of recording every detail likely to be useful for the compilation of statistical tables. Among other things the official records cover all matters of moment to the general health of the public. At my request, and through the courtesy of Cav. Alessandro Escoffier, the following table was specially prepared, a glance at which affords ample evidence of the healthfulness of the native population.

Table of Deaths at San Remo. (From January 1, 1881, to December 31, 1891.)

Year.	Permanent Population.	Single.			Married.			Children.			Total, including Foreigners.			Foreigners.			Natives.			Death-rate per 1,000.
		Males.	Females.	Total.	Males.	Females	Total.	Males.	Females.	Total.	Males.	Females.	Total.	Males.	Females.	Total.	Males.	Females.	Total.	
1881	16,189	126	85	211	55	51	106	16	25	41	197	161	358	25	13	38	172	148	320	19.75

It is unnecessary to burden this letter with a lengthy study of mortuary statistics. But the following condensed table of the principal causes of death for last year, which represents a fair annual average, may prove instructive.

Table Showing Causes of Death at San Remo for the Year 1891.

	Number of Deaths.
Respiratory organs[1]	138
Digestive organs	52
Nervous system	42
Organs of circulation	21
Zymotic diseases[2]	15
Senile marasmus	19
Premature birth	8
Constitutional affections[3]	8
Suicide and dentition each	1

Infant mortality is large at San Remo, but this circumstance has no bearing on the health of the foreign winter colony. On the other hand, the undue proportion of diseases of the respiratory apparatus will convey its warning to the stranger, who should never fail to neglect obvious precautions on the Riviera. Pneumonia is of such relatively frequent occurrence that one feels tempted to assign to that malady a place among endemic infectious diseases. Be this as it may, there is no doubt that the prevalence of dust-laden high winds, and the frequent change from hot to cold, are favoring factors in the development of all acute respiratory troubles. There is little zymotic disease at San Remo. Dr. Freeman, who has built up a large practice here, informs me that in twenty-two years he has not seen a single case of diphtheria at San Remo. Other practitioners have made similar statements to me, and there is but one opinion among foreign physicians, namely that the place is essentially a healthy one. Scrofulous and tubercular diseases, more particularly phthisis, are comparatively frequent. But when it is remembered that tuberculosis has been so largely imported by strangers, including native Italians, it would be quite unjust to attribute it to climatic or local influences of an unfavorable kind. I believe the visitors to some extent prejudicially affect the health of the natives, and not *vice versa*, as has been claimed by some medical writers.

The death-rate of San Remo is certainly low, but Dr. Hassall, believes it ought to be lower. This well-known author, who since many years is a winter practitioner at San Remo, has published the most comprehensive and accurate work [1] on that health resort extant. In a note relative to sanitary and other local affairs, kindly addressed to me, he is emphatically of opinion that, with improved sanitation, the death-rate of San Remo ought to be "reduced to something like 10 or 12 per 1,000. The mortality of many of the towns in England, with a very inferior climate and with arrangements still far from perfect, does not exceed 12 to 15 per 1,000."

Just beyond the Campo Santo, the well-kept cemetery, the local Cremation Society have recently put up their attractive little building, containing a modern furnace (Venini system). A better argument for sepulture by cremation as the future method of disposal of the dead need not be sought for than the contrast afforded by this space-robbing cemetery, and the economical arrangement of suitable urns containing the remains of the departed in far less repulsive shape than any earth-covered coffin can ever hold. Cremation need never be made antagonistic to the last ceremonial rites imposed by the church. The San Remo Cremation Society already numbers one hundred and fifty members among the leading citizens of the place. Sir Spencer Wells, who is, I believe, the President of the British Cremation Society, expressed his entire approval of the arrangements existing for the expeditious and odorless accomplishment of incineration. The gasogenous Venini system, by which the body is exposed to the direct flames of intensely hot hydrogen compounds, appears to answer every purpose. The work is done in less than two hours.

The city of San Remo, fully alive to the importance of preventing the spread of contagious diseases, is now erecting a spacious public disinfectory. In every case of contagion, whether occurring in hotels, lodging houses, or villas, the entire clothing outfit, linen, bedding, etc., are to be sent to the disinfectory, where they will be subjected to the action of super-heated steam, applied in the efficient manner devised by modern science. Should any hotel-keeper refuse to comply with the ordinance now in force, the authorities have the right to peremptorily revoke his license. Every health resort would do well to introduce similar apparatus for the greater safety of the public. The expense of construction could be covered by small fees exacted for the use of the hot chambers.

[1] Under this heading there were reported 39 deaths from tuberculosis (phthisis), including 16 occurring in foreigners.

[2] Four deaths from small-pox (cases said to have been imported from France), 3 from croup, 3 from influenza, and one from measles are noted under this head.

[3] Five cases of carcinoma, *i.e.*, a large proportion.

Saint Saviour's Sanitarium for Inebriate Women.—This is an institution recently incorporated for the treatment of women addicted to the excessive use of alcohol, opium, cocaine, or other narcotics. It is under the charge of the Sisters of St. Mary, and is situated at Inwood, on the northern end of Manhattan Island.

[1] San Remo and the Western Riviera Climatically and Medically Considered. By Arthur Hill Hassall, M.D. London: Longmans, Green, & Co., 1879, and San Remo, etc. London: 1883 (a new edition of the above and more exclusively devoted to San Remo).

New Instruments.

AN IMPROVED IODOFORM BOX.

By CEPHAS L. BARD, M.D.,
VENTURA, CAL.

A STRICT compliance with the requirements of an antiseptic dressing demands that iodoform, when used, should reach the wound in a sterilized condition. Applied with a brush, sprinkled from boxes or jars, through a covering of antiseptic gauze, or sprayed by powder-blowers, its use is to be deprecated, as neither during its storage nor in its distribution, is the powder sterile. From an æsthetic point of view, such employment is also objectionable, being lacking in neatness and precision.

Far superior and preferable is the application of this and similar powders by means of the well-known Gerster iodoform box, which can be readily sterilized, and with precaution will retain its contents, if rendered so before introduction, aseptic indefinitely. From it, however, the powder, issuing through its cribriform distributing plate, in an unvarying circular stream, cannot be regulated to conform with the needs of the varying forms of wounds, sores, and ulcers.

I wish to call the attention of the profession to a device of my own, an improvement on the box just mentioned. Its output can be accurately adjusted and made to assume linear and annular forms, so that it will adapt itself to a sutured incision or to a circular ulcer.

By reference to the illustration it will be seen that, so far as its upper portion, or top, is concerned, it does not differ from the Gerster box, being provided with a circular cribriform distributing surface, protected, when not in use, by a screw-cap.

A radical difference will be noticed, however, in its lower portion. The bottom is open for the purpose of filling, and is covered by a screw-cap. The periphery of the lower portion of the box, or barrel, is pierced by equi-distant cribriform openings, rectangular and circular in shape. Rotating on this portion is an annular collar, or ring, furnished with but one circular opening. Ordinarily, the circular opening of the rotating collar rests between two of the cribriform spaces beneath, and rotation of the band is prevented by the lower screw-cap bearing normally against its lower edge. So arranged, leakage of the contents is impossible.

When required for use, a turn to the left of the screw-cap permits rotation of the collar, and an alignment of its circular opening with those beneath, secures an outpour in the desired form and quantity.

When a large application is indicated, the upper distributing plate, as in the Gerster box, is called into requisition.

Those Thirty-two Bites.—Dr. Lauder Brunton, in the course of a recent lecture on "Mastication," at St. Bartholomew's Hospital, made use of the following remarks: "I think it was a magnificent stroke of genius on the part of the President of the Royal College of Physicians, Sir Andrew Clark, when he informed Mr. Gladstone that he had one mouth and thirty-two teeth, and that for every mouthful of food he took every tooth should have a chance, so that he should take thirty-two bites to every mouthful. And," continued Dr. Brunton, "if the patient has lost some of his teeth, he should allow two bites for every missing tooth, and even that will not always do if many teeth have gone."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 6, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	29	9
Scarlet fever	46	3
Cerebro-spinal meningitis	3	7
Measles	193	15
Diphtheria	55	21
Small-pox	7	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

An Ancient Epigram and a Modern Instance.—The *British Medical Journal* states that one of the physicians of the Glasgow Western Infirmary objects to his patients being handled on cold mornings by students having cold hands. In order to call attention to this evil, complained of anciently by Martial in his epigram to Symmachus, his physician, the Glasgow professor offered a small prize for the best translation of Martial's epigram:

> Languebam; sed tu comitatus protinus ad me
> Venisti, centum, Symmache, discipulis.
> Centum me tetigere manus Aquilone gelatæ.
> Non habui febrem, Symmache; nunc habeo.

The committee has decided that two of the translations are equally good. One is by Mr. J. F. R. Gairdner, after the manner of Burns:

> Smart cam' ye, sir, to me na weel,
> A hundert students at your heel;
> A hundert hauns did ower me feel
> Wi' Boreas blue.
> I had nae fever then, but, deil,
> I have it noo.

The other rendering, by Mr. J. F. Gemmill, reads:

> I lay in number twenty-one, a case for rest and tonics,
> And good old G—— came round to me with all his train of chronics;
> A hundred meds., with fingers blue, palpated me like Lister,
> And now, no longer weak and cold, I'm frizzling like a blister.

Pretty poor translations both.

The Doctor as a Debtor.—There is a good deal said in medical journals about the doctor's bills and the hard time he has to collect them. It seems that there are doctors who are debtors, and who are not very responsive to just monetary claims upon them. We are rather glad that the Cleveland boy, as narrated below, got the best of his debtor. The boy in question had as a customer a certain South Side doctor. When the physician's bill reached $1 the boy presented it. It was hard to collect. The boy called several times, but the doctor never had the dollar. The physician moved away and the lad lost sight of him for a time, but finally located him on the West Side and renewed his attacks. At last one day he told his mother he would make one more effort, and then if that were not successful he would give it up. Accordingly he went to the doctor's office and found the doctor out. But inside the door hung the customary slate. On it the boy wrote. "Call at —— Street, William Smith." The doctor called and the boy saw him coming up the street. He told his mother what he had done, and said: "Now, I will go and hide, and you can show him the bill." "I will do nothing of the kind, Willie Smith," said the lady, "and you ought to be ashamed of yourself." A young lady visitor in the family thought more of the scheme and, confronting the doctor at the door, presented the bill. The professional man said that the joke was on him, paid the dollar, and went away laughing.

WINTERING IN EGYPT.

BY FREDERICK PETERSON, M.D.,

CHIEF OF CLINIC, NERVOUS DEPARTMENT, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THERE is probably no other country in the world so delightful as Egypt for a winter sojourn. It is equally fascinating for the traveller in search of recreation and for the invalid in quest of health. One is placed in an environment at once tonic to the mental and physical organization. The western mind, whether healthy or morbid, is certain to be both pleasantly impressed and deeply stirred on beholding strange races, curious costumes, oriental manners and habits, Saracenic architecture, a land of deserts, oases, palms, and the river Nile, a land abounding in magnificent monuments of an ancient civilization, and over all of which hangs unchangeably a vivid, cloudless, splendid sky. Change in itself is always a tonic, strong in a direct ratio to the amount of novelty, and where this therapeutic agent is indicated in its most powerful form, Egypt must be the prescription.

For the invalid Egypt has remedial qualities which are entirely her own, and not to be found elsewhere, modes of life which are restful, peculiarities of climate which are unique. It must be taken into consideration, too, that this desirable resort is not so far from our shores as it may seem, and that the time of travel is being gradually reduced. Alexandria is five or six days from London. It is but twelve to fourteen days from New York (North German Lloyd to Genoa eight to nine days, rail to Brindisi one day, P. & O. steamer to Egypt three days; or, to Paris eight days, rail to Marseilles fourteen hours, French packet to Alexandria four to five days.

Egypt is a narrow green ribbon of land, with the Nile, not as broad as the Missouri River, flowing through it, and endless stretches of desert on either side. These thousands of square miles of barren dry sand rob the air of most of its moisture, dissipate clouds and prevent rains, and completely sterilize the atmosphere of pestiferous germs.

The climate of the Delta is not treated in this article, because no part of it can be considered a health-resort for Americans or Europeans (many residents of Egypt spend their summers at Ramleh or Alexandria), and because it differs materially from the rest of Egypt. For instance, Cairo, which lies at the upper angle of the Delta, has twelve rainy days in the year, while at its other extremity, Damietta and Alexandria, rain is still more frequent.

Interesting and charming as Cairo is to most people, it is not here that the invalid should take up his winter residence, although he may make it his headquarters from which to depart on his various excursions. The general sewer system of Cairo is in very bad condition, but those of most of the hotels are good. The mortality of Cairo is extraordinary, almost equal to that of Madras. The Cairo death-rate is 46 in 1,000; Madras, 48; Paris and Berlin, 23.50; London, 17.4. In winter one may spend some very miserable, cold, damp days in Cairo, for the hotels are rarely provided with means of heating the rooms, and few of them have a sufficiency of chambers with a southern exposure. I experienced about Christmas time, last year, four most uncomfortable rainy and cold days in succession in Cairo, and suffered more from it than one winter month in Florence, some years ago, treasured up as one of my bitterest memories of disillusion in sunny Italy.

Season.—The season for tourist or invalid is the seven months from October to April, inclusive, but one may remain through May without discomfort. The other months are objectionable because of the heat and the inundation of the Nile.

The seeker after health has one of three courses open to him on reaching Egypt. He should either go into winter quarters at Helouan, Gizeh, or Luxor—take a dahabeeyeh voyage up the Nile for three or four months, or go on camping excursions in the desert. This last suggestion will be a novel one, I think, to the European physicians who send patients to Egypt and to the physicians residing there, but it was very apt to occur to an American physician, familiar with some of our tent hospitals and the benefits to great numbers of invalids, especially consumptives, of camping trips in our Rocky Mountain regions. Camping has advantages in Egypt, too, that are never to be obtained in America, the absolute certainty of warm sun and rainless days, and the means of carrying any quantity of necessities and luxuries in the way of edibles and household furniture.

Before describing specifically these courses, however, it will be well to consider the climatological features of Egypt in detail. Most of the observations at our command have been made at the Khedivial Observatory at Cairo, and while these answer fairly well for Helouan and Gizeh, which are in the immediate neighborhood of that city, there are unfortunately no elaborate records as yet available to throw light upon the climatological conditions at Luxor, four hundred and fifty miles farther south, or out in the desert at various distances from the Nile Valley. Dr. F. M. Sandwith, of Cairo, in his admirable book, "Egypt as a Winter Resort," has made a careful study of the observatory records, and also of such others as have been communicated by physicians in their journeys up the Nile, and to this book I am mainly indebted for the following statistical facts as to the Egyptian climate—where it seemed to me advantageous for the reader. I have introduced figures for comparison with other health-resorts.

Elevation above Sea-level.—Helouan, Gizeh, Cairo, 100 to 200 feet; the Mokattam Hills, just back of Cairo, 600; Luxor, 292.

Temperature.—The Cairene isothermal line runs between Algiers and Santa Cruz, and Florida and Canton. Freezing-point is never reached in Cairo, but absolute minima of 35° and 36° F. were noted on two nights in January, 1887 and 1888, respectively. The desert is sometimes piercingly cold at night, as I found in a camping trip to the Wadi Natroon. Water in a shallow dish will occasionally freeze on exposure to a desert night wind. The thermometer readings for the seven seasonable months may be best judged by reference to the following table (Fahr.):

	Mean of Maxima.	Mean of Minima.	Mean of Means.
	Degrees.	Degrees.	Degrees.
October	84.0	64.8	74.3
November	74.2	56.3	64.4
December	67.7	50.4	58.4
January	61.4	46.6	53.6
February	65.3	48.8	57.0
March	73.2	53.0	62.8
April	81.2	59.9	70.4

Rainfall.—Cairo, a trifle over one inch annually, distributed over twelve to fifteen days of the winter months. The same figures for Helouan and Gizeh. At Luxor it is not quite true, as has been facetiously stated, that "it rains only once in 4,000 years," but rain is so rare a phenomenon that the date and duration of a shower are carefully recorded, not only by Luxor residents, but by transient travellers, as an extraordinary experience. Showers were noted once in 1878, once in 1882, once in 1887; and Dr. Boase remarked a three-minute rain in 1888.

It is interesting to compare statistics as to the annual rainfall in various resorts, although this is not as important as to ascertain the number of cloudy and rainy days at any health station during the season.

	Annual rainfall in inches.	Number of rainy days during seven months; winter season.
Luxor	Minute fraction of inch, if any.	Usually none.
Cairo	1	12
Hyères	33.50	32
Algiers	32	71 (six months)
Pau	43	50 (six months)
Nantucket	45	91
Aiken	46.48	41 (six months)
Jacksonville	55.93	72
Denver	11.41	39
Los Angeles	13.13	45
White Mountains	50	87

Dew.—In Lower Egypt, along the Nile, and in the desert near the Nile, dews are always present, so that walking in the green fields at night, and up to nine o'clock in the morning, is unpleasant. At Luxor and the First Cataract, dew is almost unnoticeable.

Humidity.—The most valuable feature of the Egyptian climate is its dryness. At Cairo the relative humidity is least in June (44), and the annual average relative humidity is 58.4; but for the seven months during which Cairo is frequented by invalids, the average is higher, 63.2 (London over 90 in winter). This I base upon Dr. Sandwith's table from the Observatory records for five years. It must be remembered that this Observatory is situated near the river and at the apex of the Delta. Often, even at Cairo, the humidity on individual days is phenomenally low, for instance, down to 3 one day in April, 1887, and once 4 in March, 1888. These figures apply also to Helouan and Gizeh. As regards the humidity at Luxor, there are as yet but few figures at command, but from such as have been taken, we learn that the air there is much dryer than at Cairo, the average being twelve to fifteen per cent. less. Thus far no observations as to this important particular have been made in the desert proper, remote from the Nile. Undoubtedly there the humidity is still less, probably the least of any place in the world, and it is to be hoped that desert records will ere long be made. The following table will illustrate the difference in mean annual humidity of various places in the world.

Luxor	50.5	Asheville, N. C. (Gleitsman),	70.10
Cairo	58.4		
Greenwich	87.0	Mt. Washington	86.00
Algiers	70.7	Florida (Jacksonville)	68.00
New York	73.0	Adirondacks (Skinner)	70.5
Aiken (Geddings)	64.04		

Air-pressure.—The barometric readings at the Khedivial Observatory for five years, show an average of 29.86, never above 29.99 in any month. Comparing this mean air-pressure with some other health-resorts, we have:

Cairo (Sandwith)	29.86
Nice (Collier)	29.60
Hyères (Cormack)	30.16

Clouds.—Not infrequent at Cairo. In the desert and at Luxor, almost unknown.

Winds.—The prevailing wind at Cairo is from the north; in January, however, from the southwest. The average force in miles calculated by the anemometer is 2.9 for the year, but for the seven winter months it abated to an average of 2.3.

At Luxor the prevailing winds from November to March, inclusive, are southwest, northeast, and northwest, and the average force in miles for these five months is exceedingly low —.9.

None of the winds in Egypt are uncomfortable or dangerous, like the föhn, mistral, sirocco, and solano, of some other resorts, with perhaps the exception of the khamseen. Khamseen is the Arabic word for "fifty," and the wind is thus named because it is apt to blow during some of the fifty days following Easter Monday. The number of khamseen days in a year varies from 4 to 20. It blows for three days as a rule, but may continue longer. It is very dry and hot, and the air is commonly loaded with fine sand. It comes from the south or southwest. I experienced one day of the khamseen in the Lybian desert while travelling by camel in a small caravan, in January last, but did not find it very uncomfortable. According to Dr. Sandwith, "the general effects are a little excitement and stimulation of the system, a more rapid succession of ideas, and increased action of some of the functions, followed by listlessness, headache, and languor."

Water-supply.—The water of the Nile, or of wells in the Nile Valley, is, of course, used altogether by the residents. Visitors often drink nothing but bottled waters, such as Apollinaris and Giesshübler, but with proper filtration there is no water in the world superior to Nile water for drinking purposes. The Cairo water company filters its water. Every dahabeeyeh and steamer on the river, and every house in Cairo, and other large towns, is supplied with huge earthen jars, through the bottom of which the water filters pure and glistening drop by drop. This is on the same principle as the Pasteur filter now coming into general use in America and elsewhere, and it answers the purpose perfectly. It is needless to say that unfiltered water should never be drunk in Egypt.

Prevailing and Uncommon Diseases.—Diarrhœa is common among the natives, and visitors occasionally suffer from it unless they are duly cautious as regard warm abdominal clothing. Typhoid fever, typhus, measles, and relapsing fever are not infrequent in the overcrowded and filthy native quarters, and there are some forty deaths from small-pox in Cairo annually. Diphtheria prevails to a certain extent. Scarlatina, whooping-cough, and mumps are very rare. Pleurisy, bronchitis, and pneumonia are frequent, but only from a careless exposure at night; for the night is often a strong contrast to the day in point of temperature. Malaria in a mild form is frequent along the river in the warm months.

Consumption is almost unknown. The Egyptians seem scarcely ever to have it, but the blacks from the far South (Nubia, Abyssinia, Soudan), on coming to Lower Egypt, which is damp and cold in comparison with their native land, are subject to it.

Entozoal disorders are common, and I saw several cases of anchylostoma duodenale with Dr. Sandwith at the Kasr-el-Aini Hospital. Ophthalmia as is well known, is extraordinarily prevalent in Egypt, and has been for thousands of years, but foreigners seldom suffer from it. Sunstroke is rarer than one might suppose, and the remarkable precautions taken by some tourists to protect their heads are quite unnecessary.

Acute rheumatism, gout, and rheumatoid arthritis are practically unknown in Egypt.

I was myself especially interested in insanity and nervous diseases among the Egyptians. Elsewhere I have called attention to the phenomenal rarity of insanity and the entire absence of paralytic dementia among the Egyptians.[1] Egypt, with six millions inhabitants, has but

[1] Insanity in Egypt, by Frederick Peterson, MEDICAL RECORD, May 21, 1892.

one asylum, containing two hundred and fifty inmates, whereas New York State, with the same population, has over fifteen thousand insane in its numerous asylums.

I observed several cases of chronic poliomyelitis, and numerous infantile spastic paralyses, most of them making a living by begging through the streets or around monuments and tombs. The climate of Egypt is so favorable, and food so cheaply and easily obtained, that such cases as would with us be put into hospitals for incurable diseases, here live out-of-doors, sleeping where they like, and satisfying their hunger with a piece of native bread thrown to them, and an onion or two taken from a neighboring field. Wherever I would go I found it easy to establish an out-of-door clinic, for as soon as it was understood that I was a physician, my tent or boat would be sought by any number of applicants for medical advice and drugs.

Diseases Improved and Cured by the Climate of Egypt.—This climate is invaluable in all manner of chronic diseases of the respiratory organs; for delicate lungs or incipient phthisis, for rheumatic affections, for convalescents from any acute disease. As Dr. Sandwith aptly remarks, the most important question really is to determine what kinds of patients *not* to send to Egypt. As to this, each consulted physician must decide upon the merits of individual cases. It is almost needless to say that moribund phthisical patients, or invalids with apoplectic tendencies, should not be sent to Egypt.

There is no doubt that a voyage on the Nile, or a residence in Cairo, Gizeh, Helouan, or Luxor, or camp life in the desert, is a valuable indication in many forms of nervous and mental disease, such as neurasthenia, insomnia, over-work, hypochondriasis, hysteria, melancholia simplex, and other mild forms of incipient or threatened insanity. There is no better climate for intractable rheumatic and malarial neuralgias, sciatica, and the like.

Having given these preliminaries, it now remains to consider briefly the means of taking the best advantage of what Egypt offers to invalids.

Gizeh, Helouan, Cairo.—On reaching Egypt one disembarks at Alexandria preferably (though one may also land conveniently at Ismailia), and then makes his way by rail at once to Cairo, where he takes a sunny room at one of the good hotels (Shepheard's, Continental, New, or Royal), and prepares his plans for the winter. If a physician is needed there are many good English and German physicians in Cairo.

Gizeh and Helouan are the sanatoria of Cairo. Both are in the desert, and both within easy reach of the city and good medical care.

At Gizeh, seven miles from Cairo, is merely an English hotel (the Mena House) on the edge of the desert, and almost in the shadow of the three great pyramids and the Sphynx. It is as perfect in all of its appointments, sanitary arrangements, water supply, etc., as any hotel can be. Rooms with fireplaces and sunshine can be obtained. Horses, carriages, camels, and donkeys are on hand. A coach runs to the city daily. There is a good library and reading room, billiard-room, tennis-court, golf links, archery and cricket ground, swimming-bath, and a resident physician. The advantages here are the warm, dry, aseptic air of the desert, the quiet surroundings, the nearness to Cairo, and the interesting monuments of antiquity.

Helouan I have described more in detail in another article.[1] It lies fifteen miles to the south of Cairo, and is reached by numerous trains daily in forty minutes. I will say here that the Egyptian railway trains are much superior in point of comfort and speed to most continental trains. There are two hotels at Helouan, and there are a great many pretty villas that may be hired for the season. The village is about three miles from the Nile, and very near the great cliffs of the Mokattam range. The chief attraction here is the sulphur, iron, and saline thermal springs. The baths are well constructed and under European supervision. This is the place *par excellence* for chronic rheumatism and gout. One is really within easier reach of Cairo here than at Gizeh. The desert surrounds the little town. There are the usual amusements of a spa in Europe, and in addition historical attractions—the ancient quarries near by, and the pyramids of Sakkarah and remains of Memphis just across the river.

Luxor.—It has already been stated that Luxor is dryer, warmer, and sunnier than any of the resorts about Cairo. By next season there will probably be trains running the whole distance of four hundred and fifty miles from Cairo, south to Luxor, but at present one takes a sleeping-car to Assiout (twelve hours), and goes thence by steamer or dahabeeyeh. Luxor has two good hotels and an English physician. The town has four thousand inhabitants. Close by are the temples and ruins of Luxor, Karnak, and Thebes. There is postal and telegraphic communication with all parts of the world.

The hotel prices in Egypt are all rather below those charged in most American health-resorts.

These three places, Gizeh, Helouan, and Luxor, are the chief, in fact the only, resorts in Egypt for invalids who intend making, or are compelled to make, a protracted stay in a hotel. I have no doubt that in time other and still better sanatoria will be established in spots still better adapted to make use of the wonderful properties of the desert climate—places perhaps remote from the Nile and its seven inches per month of evaporating water, and which will be desert health-resorts in every sense of the word.

The Nile Voyage.—If there is anything in life which will steal away worries and cares, soothe the tired brain, calm the unstrung nerves, bring back vagrant sleep,

> "Administer to a mind diseased,
> Pluck from the heart a rooted sorrow,"

it is the dream like voyage on the Nile in a dahabeeyeh. At an expense of $600 to $800 per month four people have a house-boat, four bed-rooms, dining-room, sitting-room, bath-room, large deck with awning, captain and crew of eight to ten or more men, cook, waiter, interpreter, and food for all. One may, if one wishes, pay twice as much for the same thing, for there are always tourist companies or dragomans willing to receive it, but it is not necessary, as I have demonstrated by experience. In a dahabeeyeh you are the plaything of the wind, but although I have spent as many as eighteen days on one occasion in traversing a distance of one hundred and eighty miles, owing to contrary winds, there never was a day or an hour that hung heavily on the hands, for there is so much to do and so much to see. Perhaps this voyage has the peculiar and rare quality of making *dolce far niente* appear in its busiest aspect. At any rate, one is so much occupied with something that the weeks pass before one realizes it. This is not the place to describe how this illusion is produced of being very much occupied, when you are in reality resting and imbibing new vitality, mental and physical; books enough have been written about it to dam the Nile, as someone has observed, and to these the reader is referred for further particulars.

As there is no means of heating a dahabeeyeh on cold nights, braziers not being advisable, a Rochester lamp burning in the sitting-room will be found to answer every purpose. An assortment of books, some guns, a telescope, a photographic outfit, and other instruments, scientific or musical, which individual tastes may suggest, will be found useful and agreeable adjuncts to such a trip. The voyage should begin about mid-December and be continued at pleasure for three or four months.

The advantages of the dahabeeyeh voyage over residence in one place are obvious. There are the same climatic features as elsewhere in Egypt. It is like living in one's own home instead of in a hotel. There is change every day, and indeed every hour.

[1] An Ancient Spa, by Frederick Peterson, New York Medical Journal, 1892.

No other river in the world could be travelled in this way. The dahabeeyeh would never be a success upon the Indian River, St. John's, Hudson, or Mississippi. It might be on the Amazon. But all along the Nile are famous ruins, temples, tombs, relics of the world's most ancient civilization, which in themselves excite the interest of every traveller, whether in good or poor health.

The secret of being happy, and at the same time economical, on the Nile is to avoid the Scylla of Thomas Cook & Sons and the Charybdis of the dragomans. Cook's steamers will do very well for the wildly-rushing tourist, who is willing and perhaps able to endure any amount of haste, crowding, and discomfort. The Cook Nile steamers remind one forcibly of the old-fashioned second-rate local Mississippi freight and passenger boats. Invalids should be recommended not to travel by them. A tug to tow the dahabeeyeh is another evil that affords no adequate compensation for its noise and smoke.

Cook & Sons have dahabeeyehs also, their charges being three times what one can be obtained for by application to private owners. The average dragoman asks only twice as much as it is worth. By hiring an interpreter for the voyage and exercising only a little discretion and supervision in purchases and payments, the Nile voyage comes within the means of many people of moderate circumstances whom Cook's prices would otherwise debar from its advantages.

Camping-out in Egypt.—Camp life in Egypt is something luxurious. I have camped out on shooting expeditions in Nebraska, Dakota, and other Western places, and endured hardships that I should not care to experience again. But in Egypt, where labor and carrying cost next to nothing, where everything in the way of furniture and supplies can be stored away somewhere on a camel, where every day can be foreseen to be rainless and beautiful, life in tents becomes a pleasure.

It is always well to have some objective point in view to reach, and among the pleasantest desert trips with tents and camels are those to the Sinaitic Peninsula, to the Natroon Lakes, to the Fayoum, and to several other oases to the west of the Nile. Probably the warmest and dryest for an invalid would be that from Assiout, Geergeh, or Eseh to the Great Oasis. But one may camp on the edge of the desert, travelling southward along the Nile, in that way having the advantage of more interesting surroundings; for some people might find the desert monotonous. For those who enjoy shooting, camping in the Delta or the Fayoum, or anywhere along the Nile affords ample opportunity for the gratification of this taste. There is nowhere in Egypt any very large game; a few wild boar, hyenas, jackals, wolves, foxes, and unattainable gazelles, ibex in Sinai. But this land is the winter home of all the European aquatic birds, apparently, and wild pigeons, snipe, quail, plover, also abound in phenomenal numbers. As for quail, we shot about one hundred and twelve in three hours with three guns, two of us being indifferent shots. We made shooting excursions through the Delta, to the oasis of the Fayoum, and to Wadi Natroon. As an example of the methods of camping here, I will briefly describe our equipment for the trip to Wadi Natroon, where we spent ten days. We were a party of three, and had eight camels with their drivers, a dragoman (interpreter), desert-guide, cook, hunter-guide, and a boy, two tents, three folding bedsteads with mattresses, two folding tables, chairs, rugs, cook-stove, fuel, water, rifles and shot-guns, and provisions for all the party, camels included. Camel-riding becomes easy after a time. One can assume almost any position, even lying down and going to sleep, and one can read with ease. Ladies are not at all debarred from taking such trips. Everything necessary can be procured in Cairo, and the expense should not be over $5 to $7 per day for each traveller.

While we in America frequently enough recommend camp life in the West to certain of our patients, I believe thus far it has never been advised by authorities on Egyptian climate, probably through lack of familiarity with its value and practicability.

Clothing.—Winter clothing should be used in Lower Egypt, autumn clothing in Upper Egypt, and in the desert and on the Nile. Heavy wraps will be found useful at night.

Books.—The best book of reference for the physician and invalid is Dr. F. M. Sandwith's "Egypt as a Winter Resort" (Kegan Paul, Trench & Co., London). The best popular literary book is Charles Dudley Warner's "My Winter on the Nile." Both Baedeker and Murray publish guide books, one of which is indispensable.

THE PATHOGENESIS OF GONORRHŒAL JOINT AFFECTIONS.[1]

By HENRY S. STARK, A.M., M.D.,

NEW YORK.

Without wishing to exaggerate the importance of this form of venereal disorder, it is not claiming too much to assert that of all gonorrhœal complications it is one of the rarest, the one whose pathogenesis is least understood, and the one least amenable to our modern therapeutic resources. It would appear that the results of the activity which now pervades every department of medical thought would supply the information lacking to fill up the *lacunæ* in our knowledge regarding the etiology of blennorrhagic arthropathia, or that recent bacteriological studies would furnish us with the missing data; the fact of the matter, however, is that our hopes in this direction have not been fully, but only partially, realized.

From the time that this subject first engaged the minds of original thinkers until the present day, a number of theories of its origin and of its connection with blennorrhœa have been extant. The discovery, however, of the gonococcus necessarily threw several of these theories out of the field, while it helped to confirm certain others which were based on the investigation of pathogenic micro-organisms.

Ever since the causal relation between gonococci and gonorrhœa has been firmly established, the channels of investigation have been running in one direction; namely, establish the pathological anatomy of blennorrhagic arthritis upon the presence of specific micro-organisms in the secretions derived from affected joints. In the light of our present knowledge, therefore, any theory which does not recognize this genetic correlation must be rejected as being inadequate to the requirements of modern medicine.

Besides the doubtful pathology of this blennorrhagic complication, there are other important and characteristic features connected with the disease, which make the subject under consideration of more than usual interest. Its rare occurrence, its occasional severity, and remote results, such as anchylosis, and hydrarthrosis; its usual recurrence in the same individual with subsequent attacks of gonorrhœa; its occurrence, frequently in the absence of any discoverable tendency to the gouty, or the rheumatic diathesis; its disposition not to respond to the usual antirheumatic agents; all combine to form a complex of phenomena which invests this disease with an air of mystery and misunderstanding hardly commensurate with the amount of labor expended upon the subject.

Not wishing to pass in review the chief episodes in the course of the evolution of our knowledge of this subject, it will be sufficient to state that it is only in recent times that legitimate attempts have been made to account for its pathology. An historical retrospect, however, of this subject brings to light the bare fact that, though this complication was already recognized as early as the sixteenth century, the hypotheses which the earliest investigators advanced plainly demonstrate that they had no conception of its nature. Up to the present day a large amount of experimental work has been done and clinical evi-

[1] Read at a meeting of the Metropolitan Medical Society.

dence has been collected to account for its pathology, and these efforts have resulted in working a revolution in the opinion and practices of the profession. Nevertheless, there are problems connected with the pathogenesis of this complication whose solution has baffled time and men. Why this complication should exhibit an unfortunate predilection for some persons, while others should enjoy a comparative immunity; or why this affection should, in a generality of cases, reappear with its former virulence and intensity with fresh attacks of urethritis, are problems in medicine which are as deep as the Sphinx and as dark as the Sibyl

In 1886, in an Inaugural Thesis upon the "Causation of Gonorrhœal Rheumatism," based upon a personal analysis of some eight cases, I drew the conclusion that septicæmia was the true explanation of the pathological phenomenon in gonorrhœal joint affections. To-day, fortified with a more extended experience and study of the subject, I do not hesitate to adhere, with certain modifications, to the same conviction that the affection is due to the absorption of putrid secretion through the portals of the urethral veins and lymphatics. In other words, I believe that gonorrhœal rheumatism is a metastatic crisis attributable to the translation of the morbific matter from the primary seat of the disease. Now, to establish such a conclusion upon a logical basis the following conditions would have to obtain: Firstly, it would be obligatory to isolate the poisonous principles from the original and from the metastatic sites of the disease, and, secondly, it would be necessary to establish an unquestionable identity as regards the character and behavior of these toxic elements. How far the effort to establish a parallelism between the microbial elements of the primary disease and the complication under consideration has progressed, becomes evident when we pass in review the chief events in the modern history of the affection. We shall then see that the disease and its complication stand in a causative relation to pathogenic bacteria that are similar in size, shape, behavior, arrangement, and color—in other words, are completely identical. The first event was the discovery and establishment upon bacteriological and clinical evidence of the specific poison of gonorrhœa. The second event was the discovery of the same gonococci in the exudates of persons suffering from the blennorrhagic joint complications. There are up to date a number of such discoveries on record. Thus Hall, Wyszemski, Volkman, Smirnoff, Petrone, Horteloup, Kammerer, Hartley, and others, were enabled to demonstrate the presence of gonococci in the pus derived by puncture and incision into blennorrhagic joints. There is, however, still one link missing in the chain of proof to establish the unquestionable identity between the cocci of blennorrhœa and those found in the exudates of blennorrhagic joint affections, and that is the fact that none of the experimenters who found gonococci in the exudates of gonorrhœal joint secretions went so far as to make cultures and inoculations of the virus. When once this procedure has been satisfactorily accomplished there can be no longer any justifiable scepticism as regards the nature of gonorrhœal rheumatism and its mode of connection with gonorrhœa; for then the set of conditions which bacteriologists claim should exist before a specific disease can be attributed to a specific organism, will have been satisfied.

There exists, then, reasonable ground for believing that the toxic elements of gonorrhœa and gonorrhœal rheumatism are identical, but the fact that other pathogenic organisms can be demonstrated in these exudations, namely, the characteristic pus-generating cocci, seems to cast an element of doubt upon the conclusion drawn in this paper. Does, in point of fact, the presence of streptococci in these exudations weaken our argument? On the contrary, I think it furnishes corroborative evidence that my premises and conclusion are logically true; for we know that the favorite habitat of gonococci is within the pus-cells or leucocytes, and that this peculiarity belongs almost exclusively to the gonococci, and represents its main biological characteristic. There is, so to speak, an inseparable connection between gonococci and streptococci. In other words, blennorrhagic processes belong to the category of "mixed infections," and it is, therefore, more than likely that the secondary or complicating blennorrhagic processes belong to the same type of infection. Still another biological feature of the gonococcus, of interest in connection with study of the pathogenesis of this complication, is the tendency of this diplococcus to penetrate the intercellular substance of the mucous membrane, and thus invade its subepithelial structure, where, by coming in contact with the lymphatics, it may find an avenue of entrance into the general circulation, and an avenue of exit into or about an articulation. This penetrating or migratory faculty of the gonococcus is well known, and offers a very reasonable explanation for its appearance in different and distant parts of the body. Now, when we study the life-history of the gonococcus in the living economy on such lines of investigation, we are almost forced, unprovisionally, to accept the conclusion that this organism is the active agent in the causation of the blennorrhagic joint affections. There are other grounds for believing that gonorrhœal joint complications are merely remote localizations of the specific poison of the original gonorrhœa. Thus the study of numerous cases has demonstrated with tolerable certainty that blennorrhagic arthritis is never observed to follow pseudo-blennorrhagic processes such as a benign urethritis or a balanitis.

The pathology of gonorrhœal arthritis differs in no respect from that of arthritic inflammations occuring from other causes, except as far as may be modified by the particular specific poison. There are the same morbid inflammatory products—fibrin, serum, pus, leucocytes, micro-organisms, epithelial, bony, and cartilaginous *débris*, derived from the usual sources, with the same tendency to the formation of plastic adhesions which may permanently and seriously impair the normal functions of the involved joint. There are also the same stages of the inflammation: Firstly, the period of congestion or engorgement, then of exudation, then an organization and moulding of the exudate to conform with the contour of the parts involved. In the favorable cases the inflammatory process terminates by resolution and absorption of the inflammatory products, while in the unfavorable cases the process goes on to suppuration and partial disintegration of the bony and cartilaginous structure. In one set of cases the serum predominates, forming an appreciable hydrarthrosis; in another set of cases the pus predominates, forming a pyarthrosis. In several cases that came under my observation, the articular ends of the bones became thickened after the subsidence of the acute symptoms, and remained permanently hypertrophied, producing an incomplete anchylosis. The types of gonarthritic inflammations conform also to the types of arthritis from other causes, such as the traumatic infectious diseases, septicæmia and pyæmia, or from such constitutional dyscrasiæ as syphilis or tuberculosis. Thus we may have a typical arthritis or a periarthritis of an acute, subacute, or chronic variety, and involving one or more articulations.

It may then be claimed that there are no pathognomonic pathological features peculiar to blennorrhagic joint affections, excepting the presence of the gonococcus, which would in all or even in most cases permit them to be differentiated from joint affections due to other causes. There are, however, certain clinical and etiological factors which permit us to ascribe to gonorrhœal arthritis a special clinical picture that renders the differentiation comparatively easy. The enumeration of these signs or guides does not properly come within the scope of this article. In pursuing the study of the origin and development of gonorrhœal joint affections, I have purposely omitted from the discussion the consideration of certain views, from the conviction that they bear the stamp of

age, and are not based on bacteriological evidence, which, to-day, is the crucial test in pathology. Such views are the "vaso-motor theory," which seeks to explain the complication as a reflex vaso-motor disturbance starting from the original inflammation in the urethra; another view is that the joint complication is simply a coincidence in persons whose systems are depressed by some taint, as the rheumatic or gouty diathesis. In other words, that the simultaneous occurrence of the disease and its joint complication, is merely accidental. It must be very evident, even to the casual observer, that such theories, in the light of our newer knowledge, must be relegated to the realms of antiquity. For experience and experiments go to show that the gonococcus is the determining and decisive element.

In describing the area of infection in a typical case of acute blennorrhœa, we must not think it necessary to stop with the invasion of the urethra in the male any more than we would with the vagina in the female, for there cannot be any doubt that in a very large proportion of cases the process of invasion extends to other organs and tissues of the body. Thus writers speak of blennorrhagic endocarditis, blennorrhagic exanthemata, blennorrhagic ophthalmia, iritis, and sclerotitis, blennorrhagic adenitis. Why this extension should occur in some cases and not in others, I cannot suggest any explanation, except to allude to the varying propensities and vitality of this diplococcus, to the idiosyncrasy of the individual attacked, and to the condition of the soil which harbors the gonococci.

These conditions furnish the inquirer with a clue, and seem also to suggest an explanation for the peculiar immunity on the one hand, and the predisposition on the other hand, of certain individuals. In the absence, however, of sufficient observed facts unanimity of opinion is well nigh impossible.

201 West Fifty-fourth Street.

"PHYSICIAN, HEAL THYSELF."[1]

By C. B. MEDING, M.D.,

new york.

Living in an age universally progressive, it is not a matter of wonder that in the march of erudition the student should be remembered. The desire that prompts the possessor of a fine painting to seek a suitable hanging exists in nature as a principle, and all progression, to be permanent, requires progressiveness for a habitation. Now, the rapid advance of physiology, pathology, chemistry, and therapy demands for its application an equal improvement in mentality. Medicine exacts more than passive affection in its accepted admirer, it must have first equality, and then reciprocal passion.

However sad may be the fact that medical colleges require little or no education in candidates, the truth remains that no calling needs greater preparation; for appreciating the results so ennobling, including as they do that intermingling with many natures in all the secrecies of their innermost life, and that reverence which goes forth unconsciously to the sharer of voluntary confidence, I consider the true physician to hold the highest, grandest, nearest sublime of all professions. I believe that to attain to such position men should be the mental equals, if not superiors, of their race. Some consider the man well versed in a single subject the sufficient professor of the same, but is this right? Emerson says, "We have little control over our ideas, we are the prisoners of ideas; our spontaneous action is always our best; it matters little what we may assert, our final conclusion is, as has been well said, 'a pious reception.'"

I do not care to answer the pessimist's croaking complaint that there is no use seeking perfection; it is not a future possibility I look forward to as a means, but a present existence, namely necessity. There are men who combine in one profession the results of thought in all branches; such men are successful not always personally, but truly, for these are they who leave guiding "footprints on the sands of time." General excellence is a far better and more attainable goal than special perfection.

If asked my idea of medical education in the millennium I would give the socialists' creed, "In that day, man who is unfitted morally, mentally, or physically for its practice will not pretend to it." For years the two callings, theology and medicine, have received the bulk of the indifferent, undecided, mediocre youth of the country. "By the by," says Elder, "is it not a little curious that men are generally regarded best fitted for the practice of medicine who are fit for nothing else?" And why is this? Because of no necessary qualifications. Men are granted an M.D. who can scarcely put six words together grammatically; whose writing is almost illegible; whose spelling is not even phonetically passable. Such may not be unfitted; they may have passed more stringent examinations better than many M.A.'s; but in any case can it be denied that such proceeding is ridiculous, ay more, criminal? True, they may make Galens or Harveys, but what are the chances? where are the examples?

Some journals and many men are to day opposing the State legislation of medicine. I admit it seems belittling, personally I too would object; but is it not due to the community that such legislation be enacted? Under the title of doctor, how many incapable though innocent persons are doing harm? In a country where, so long as a man shows a diploma and affirms to be doing his best, he may commit murder legally, is it not quite necessary that not only the people, but also the reputable physician, should be protected?

Who has not smiled when reading Sterne, Smollett, or Fielding, at the true though unflattering descriptions of medical men? What was the cloak of such characters, what was their success due to? Simply the necessities of others. Dying men catch at straws. Any port in time of a storm.

Before civilization the wild tribe had its medicine man. Before idol or priest came He who relieved: revered, honored, and feared, He was above his people in wisdom. The medicine man has lost ground; though still the necessary frequenter of the homes of the sick, he is a humbug. Is there a way to the higher path, practical and worthy? Let us see. All the greatest men, no matter what their origin or opportunity, have been well grounded in the art and science of their time. Lucretius, Zeno, Epicurus, Aristotle, were wise in general knowledge, and later philosophers, astronomers, theologians, biologists, etc., have been polymathists. If the fathers whose eulogies we sing have not lived in vain for us, if the great who have gone before are to affect existing life for good, it can only be that in the folio of their lives, now widely open, he who runs may read the elements of success.

The thought of the physician should be logical. How can a man draw faithful conclusions whose knowledge of logic is nil?

Success with us hangs on judgment. Judgment and self-confidence go hand in hand despite any effort to the contrary. Judgment demands a keen insight added to a wide range of information.

Strength of opinion comes from but two sources—boldness and knowledge; the first falls before a bolder, but the second can only be augmented, never deposed.

Scientific treatment is based on reliable diagnosis, diagnosis logically obtained. Symptomatic treatment is the white flag of defeat.

Two factors are sure to force the medical profession to higher ground, whether it will or no: First, an universal mental advance. Second, the growing strength of public opinion.

True, there is to-day the sceptic, that strange, unbalanced, ridiculous doubter, believing nothing, accepting nothing, and if the truth could reach him, knowing nothing, being in fact a monster hypocrite. But among men mentality is greater. It would be difficult to find, at the

[1] Read before the New York County Medical Association, October 19, 1891.

present time, persons wearing frogs about their necks to cure disease, or drinking holy water at Pentecost for fever; and while there is still great faith and sale for patent medicines and secret nostrums, we ourselves have done much to encourage it. There is no reason why the various doctors whose names and faces figure on the many well known preparations, should not write and compound as good a medicine as you and I; and the fact that they are labelled useful in all diseases, is but a reminder of many brothers who have found mercury or bleeding or opium a "cure-all." It is useless to deny the tendency of the populace to acquire a knowledge of the specialties.

The motto to be placed over this age is in a word, "inquiry." From the womb to the grave, progressive man is asking questions to which every school of thought must give answer; but in answering, how have we honored ourselves? How have thompsonian, homœopathic, allopathic, vitapathic, eclectic, botanic, Christian science, and faith-curist schools answered it? I will tell you, by exaggeration, by false pretence and promise. We blame these latter, we denounce them, but are they not the parasites that have sucked their life from us? Do we not feed them? Do we not rave over and exaggerate each new notion? While we decry the era of the lancet, are we not founding an antiseptic age? While we ridicule the belief in charms and vapors, are we not establishing a microbe craze? And out of us, out of our extravagant faith in each novelty, rise up the quack and patent medicine of the day.

Public opinion, a consequent and index of public education, affects us in common with all others, by stripping the profession of every unearned honor. The silent, mysterious air is a relic of superstition and ignorance; that dignity and immensity of learning so often assumed is not proven by silence. We should rid the profession of every jot of sham honor gained by the sacredness of confidence and nearness of association, and make morality, wisdom, and character gain for it a noble reverence. Says Doctor CULBERTSON, of the *Journal*, "The province of the physician is to be more a teacher and less a dealer in drugs." The word doctor is fitly applied only to the teacher. The silence of wisdom is not aphony. If the first and highest duty of the physician is prevention, there is no better preparative than teaching. Let me read you a few verses from "The Wisdom of Jesus, Son of Sirach:" "Honor a physician with the honor due unto him for the uses which ye may have of him; for the Lord hath created him. For of the Most High cometh healing, and he shall receive honor of the king. The skill of the physician shall lift up his head, and in the sight of great men he shall be in admiration." Such words were spoken, I need not say, of but one kind of physician.

There is yet a round-faced optimistic individual who, see-sawing with the pessimist, finds satisfaction, content, and even perfection in the present; may I dismiss him with his opposite and seek truth.

Every profession has had to change its basis, not, alas! without the loss of many misled conservatives. Priests are now spiritual pastors, not confessors; lawyers are advisors, not pugilists; physicians must be teachers, not semi-magicians.

No one can estimate the injury intentional magniloquy and unconscious inconsistency have done, the ridicule they have rained upon the profession. They are the dire results of false teaching, the fungous growths springing from the light-soil, didactically taught theory, which is scattered by a host of so-called colleges over that sterile clay, ignorance.

Teaching requires thought, and thought is the hardest task in the world.[1] It is an aphorism that "scientific truth must cease to be the property of the few; it must be woven into the common life of the world."[2] How are we fulfilling the law? I will tell you—by allowing "ignorant credulity"[3] to gain the dangerous state of "a little knowledge." But while medicine is growing into the dignity of a science, we must not forget that it is, always has been, and ever will be, an art. It is an art because it must be thought, and thinking is an art.

In glancing over the past we notice a peculiarity of therapeusis; each science has at some time been its servant, and in that servitude has pushed itself forward. Astronomy leaped when men hunted for stars of destiny; physics found advance in heat, light, water, sound, and to-day in electricity, by exaggerated applications of the same to the body; chemistry is at present devoted to remedy seeking; and the various studies of psychology, philosophy, etc., find their grandest use in application to disease. Then should not the physician be as capable a master as possible remedies are slaves?

Emerson asks, "Who would speak of love or religion to a physician?" A sage has remarked that "medical men are becoming more sceptical and dangerous to the growth of ethical truth." You may deny such assertions; but is it not true that love and hate, spiritual conditions and financial transactions, are in their extremes and perversions equal etiological factors with bacteria? Are not human passions in their ebb, flood, and flow equal causes of morbidity with physical changes? And is it not true that broken or ecstatic hearts through these causes receive little treatment and less sympathy from physicians?

Probably, after this age of bacteriological research, surely some time in the future, will come the age of the study of the human mind. Sometimes it seems to me our posterity, by analysis of the past, will find mental power a great remedy. Some unknown force—mesmeric, electro-magnetic, psychologic, what you will—seems certainly to connect all minds and substances, and strangely enough, those who seem to enter into the sympathetic ego of their patients gain greatest results. Such is possible only through an understanding gotten by universal application and communion.

Every day new discoveries attract the needle of our compass, but as good mariners it behooves us to consider well all the deflections ere we set or change our course. From the days of the ancient Egyptian priests the history of medicine has been one of the rise and fall of innumerable theories and practices; but prior to the time of Hippocrates, changes were not elevated into popular manias; quiet, orderly, and dignified were the changes, teachings, and doings of the fathers.

In lieu of hero worship with its tendency to exaggerate and canonize, we have to-day a specialism not far removed—specialists of a character and number altogether contrary to the best interests of the profession, who know not dignity, not fitness, neither love nor study, but chance, and often personal dislike of remaining branches, makes the selection. What is the result? This, with a fair knowledge of one part is passed an ignorance or theoretical acquaintance of the rest. So gynecologists must examine every maiden; laryngologists must spray every throat; surgeons must operate every furuncle; neurologists see only nerves; oculists, only eyes; aurists, only ears; dermatologists, only and ever, skin. All this to the utter confounding of every principle of an upright calling, treating as they do effects for causes, symptoms for diseases, and forgetting the inseparable connection between each and every part of the anatomy.

It is an age of advance, true, but all progress is not advance. "To advance," says Emerson, "something of the old must forever mingle with the new," and that something, my dear friends, is a thoughtful *résumé*, a brief but particular condensation. For the healing of ourselves, then: A considerate following of present demands; attention to the details of modern research and discovery without necessarily an absolute surrender to the same; a wise moderation in praise; an ability to instruct; an education to prepare us for such duties.

These are the medicines we need, and it is the duty of this, of every society to urge, ay, to enforce, the wholesale manufacture and wide distribution of these remedies, toward the bettering, the elevating, the evening of this no-

[1] Emerson. [2] L. Agassiz. [3] Shakespeare.

ble calling, that they who enter its sacred portals may throw off forever that ancient oath of the Pythagoreans, to impart knowledge of this only to my own sons, teachers, and disciples, and take the new oath of civilized progress, "to acquire, to impart."

We must teach. Therapy is not the open sesame to the glorious heaven of health, but knowledge, not expressed in an incomprehensible terminology, but told in plain truth, knowledge of right and wrong, of habit and surrounding of the Hippocratean trio, "air, water, and places." Such is the golden gate to the throne of true greatness to which we of all men have a God-given right.

132 WEST 126TH STREET.

NOTES ON CONSERVATIVE OBSTETRICS.[1]

BY T. J. McGILLICUDDY, M.D.,

NEW YORK,

SURGEON TO THE NEW YORK MOTHERS' HOME, MATERNITY HOSPITAL, ETC.

THAT there are thousands of still-births every year in New York is well known by physicians who have investigated the matter, and all large cities have their proportionate share, as is shown by the records in the departments of vital statistics. Now, what percentage of these deaths is due to destructive midwifery it is impossible to determine, still it is undoubtedly quite large, and most of it is the result of meddlesome interference, followed by bungling operations by men who are ignorant of the rudiments of scientific obstetrics and whose manipulations are commonly fatal to the child and also frequently fatal to the mother. That craniotomy on the living child is still very frequently performed, and but few of the cases reported, is only too true. With the improved obstetrical instruments which I have invented, and which have been described partially in the *American Journal of Obstetrics* for December 1889, and also more fully in the *Journal of the American Medical Association* for August 8, 1891, we can certainly do away with deliberate craniotomy on the living child and leave only to be considered Cæsarean section and Porro's operation. This is, of course, in cases where the opportunity of inducing premature labor has passed. My stronger forceps is to be used in the cases of pelvic contraction of from about three to three and three-quarters inches, where craniotomy has been in times past advocated. When the conjugate diameter is two and one half inches or less and the shortest other diameter three and one-quarter inches, then Cæsarean section is indicated.

We must not forget, however, that cases have been reported where the conjugata vera was but one and one-half inch and still, from the stretching of the pelvic ligaments, or bending of the pelvic bones, or both, nature was able to bring forth a living child before the attending physicians interfered. That the ligaments stretch and the articulations of the pelvis separate is well known, and is shown by the intense pain suffered in the sacral region and the sinking in of this part during delivery. In this month's issue of the *American Journal of the Medical Sciences*, there is an abstract of an article by Hanau in *Fortschritt der Medicin*, 1892, No. 7, in which he reports his observation on the pelvic bones in twenty cases of pregnancy. He found in healthy persons an unusual growth of connective tissue without the deposition of calcareous matter. The bones examined could be cut very easily, but were not as soft as in cases of osteomalacia.

In the rare instances where Cæsarean section is indicated, if the physician in charge is not competent to perform the operation, he can easily call a consultant who can, rather than attempt, as many do, the more difficult and dreadful one of deliberate craniotomy on the living child. Embryotomy is an operation which certainly destroys one life and very frequently two, and is most often performed, where there is not the slightest excuse for it, by men who are excited, whose moral sensibilities are blunted, and who ought to be able to do better work. I do not here intend to discuss Cæsarean section or embryotomy, but simply to give the details of the following two cases and let those present draw their own conclusions:

CASE I.—Mrs. K. M——, very tall and very stout, aged forty. She was referred to me by Dr. Alfonso A. Richardson, of East Eighty-sixth Street and Park Avenue, who stated that it was her fourth pregnancy and that she had reached full term. At her other three labors, owing to some contraction at the brim and the exceedingly large size of the child, none of them had been delivered alive. Her first child was craniotomized by a professor of obstetrics in one of the principal colleges. At the time of her second and third labors, Dr. Richardson, who was in charge, informed her that when she again became pregnant, she should consult him so that he might bring on labor at the eighth month in order that he could deliver her of a living child. She refused to do so, and at the request of Dr. Richardson I took charge of the case.

The patient was at full term, and I immediately, on August 11, 1891, induced labor, and on August 12th, at 1 A.M., finding the cervix had been dilated for a long time, with the head still above the superior strait, and showing no tendency to engage, Dr. Bartlett Gilbert, who was helping me with the case, applied my axis traction forceps under ether. A fair amount of tractile force was employed, owing to the obstruction, but the advantage afforded by the handles of the forceps made the delivery comparatively easy without laceration or other injury to the child's head. The child weighed eleven and three-quarter pounds naked, and the mother stated that it was as large, if not larger, than any of her previous children.

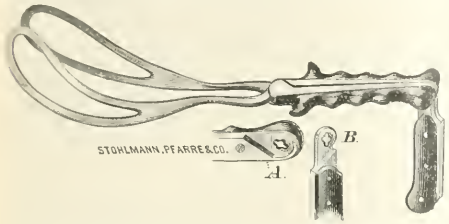
A rather profuse hemorrhage followed the delivery of the child, but this was controlled by gently kneading the uterus through the abdomen. The placenta was exceedingly large and very friable. In about twenty minutes after the delivery of the placenta another profuse hemorrhage followed, which was controlled by pressure on the fundus, the application of ice to the abdomen and inner aspect of the thighs, followed by a hot douche and ergotole injections. The patient felt weak and thirsty, with a pulse of 120 and temperature of 98° F. At 3 A.M. the pulse fell to 100, and the patient continued to vomit profusely for fifteen minutes, when she said she felt very much better. At 8 A.M., pulse, 106; temperature, 98.8° F. August 13th: At 8 P.M., pulse, 80; temperature, 99° F. August 14th: At 8 P.M., pulse, 100; temperature, 98.8° F. August 15th: At 8 P.M, pulse, 100; temperature, 98.8° F. August 16th: At 8 P.M., pulse, 100; temperature, 100.4° F. August 17th, temperature and pulse normal. Moved around in the bed a good deal, nursed baby, and said she felt well. There was no pain or tenderness over uterus; lochia normal; recovery uninterrupted.

CASE II.—A. K——, primipara, aged twenty-eight. Labor began Monday, May 12, 1891, and on Tuesday the membranes ruptured. The following Sunday, having been in labor nearly a whole week, under the care of a midwife and two physicians, she was sent to the Mothers' Home, Maternity Hospital, with a note from the physician in charge, saying that craniotomy would probably have to be performed, and that a hospital was the proper place for her. The patient was in fair condition, and on examining her I found some contraction of the conjugata vera. The head was wedged in a transverse position, which I determined by inserting my hands into the vagina. I adjusted my axis-traction forceps over the face and occiput and made traction until the head came down into the pelvic basin; I then reapplied the blades to the sides of the head and delivered a living child in the left occipito-anterior position. The side of one of the parietal bones was bruised, and there was a small slough at this point, due probably to its constant compression against

[1] Read before the New York County Medical Association, June 20, 1892.

the promontory of the sacrum. Mother and child recovered perfectly.

The advantages claimed for my axis-traction forceps are, that it is simple and uncomplicated; that it is superior to Tarnier's, because axis traction at the superior strait is perfect; that with it one has plenty of power and perfect control; that it is easy to apply, as it takes but a few



Author's Axis-traction Forceps. For the French lock, *A*, *B*, I have in some substituted a metal handle which closes like a knife-blade.

seconds, and that it has a dual character, with all the advantages of axis traction and the ordinary forceps, and thus saves the expense of buying two instruments instead of one. My friends, who have used it for the past three years, are much pleased with it. The stronger form is to be used for moderate compression of the upper portion of the infant's cranium in cases of impaction, and as an alternative for craniotomy in cases of pelvic deformity. Drs. Leischman and Barnes both say that improper instruments are the cause of a great proportion of the unfortunate results, and that what we need is power and control. Now, this instrument certainly gives one both.

776 Madison Avenue.

Clinical Department.

APPENDICITIS: WITH A PLEA FOR LESS SURGICAL INTERFERENCE IN ITS MANAGEMENT.

By LAWRENCE B. YOUNG, M.D.,

Rolesville, N. C.

The reproach of Van Helmont, "that a bloody Moloch presides in the chairs of medicine," seems not altogether inappropriate to a large class of practitioners of the present generation, when we consider the numerous cases reported in current medical literature of appendicitis for the treatment of which laparotomy seems to have swept all other measures from the field. Moreover, a reference to the most recent standard text-books on the management of this affection, restricts almost entirely the function of the physician to the duty of saying when the operation should be performed. While I do not wish to be understood as underrating the wonderful advances made in surgery in recent years, and the invaluable aid thereby furnished the physician in the diagnosis and treatment of disease, I do, however, most earnestly protest against the ofttimes indiscriminate use of the knife in this disease. One of the strongest arguments against this almost universal method of treatment seems to me to be the uncertainty of diagnosis in many of these cases; for while we are told by some high authorities that almost the only local condition requiring differentiation is *stercoral cæcitis*, a very little thought and reflection is necessary to show that there are many other conditions that closely simulate appendix disease, in the elimination of which the most careful and experienced clinicians are sometimes seriously at fault. Among the affections referred to may be mentioned: Acute intestinal obstruction; inflammation of the ovary and connective tissue in its neighborhood; idiopathic abscesses of the venter ilii, or in the course of the psoas muscle; psoas abscess from caries of the spine; renal abscess; and all descending retro-peritoneal abscesses, whether from the interior of the spinal canal, the pleura, lung, or liver. Furthermore, some of the abscesses from the causes enumerated are liable to form communications with the cæcum and still more closely to simulate primary typhlitis, which, as an independent affection, some authors consider as an uncertain and doubtful malady, but which I think occurs more frequently than some would have us believe. Another weighty objection against the prevalent practice of laparotomy is that shown by numerous post mortem statistics, which conclusively prove that a great many cases of the disease terminate in recovery without any treatment having been instituted; and last, but not least, the serious nature of the operation, for we are by no means in possession of all the fatal cases following the operation.

The brief report of a case that I recently had under observation and treatment may not be amiss. About six weeks ago I was called to see a little girl about eight or nine years of age, who had been suffering with pain in the right iliac region, nausea and vomiting, slight fever, and obstinate constipation. Upon examination I found the bowels slightly tympanitic, tenderness in the right inguinal region, elevation of temperature, and upon questioning the mother, found that the bowels had not moved for seven or eight days. I diagnosed the case appendicitis, and administered one-eighth grain of morphine, and ordered hot fomentations to the bowels, and a rectal enema; the morphine to be given in doses of one-eighth grain, sufficiently often to control the pain, continuous application to be made of the hot fomentations, and the enemas to be employed every second or third day. The patient promptly recovered. I told the mother, however, that a similar attack would be very likely to follow over-eating or any error in diet. I was summoned to the same patient a few days ago, and found the same condition, only very much intensified; the abdomen was extremely tympanitic, and the constitutional symptoms were very much more severe than in the previous attack—so much so that I could not satisfactorily eliminate diffuse peritonitis. I instituted the line of treatment previously employed with the most satisfactory results.

After I had begun to write this article I was called to see a young man, twenty-two years of age who three days previously was taken with severe pain in the right iliac region, and whose general appearance at the time of my seeing him was indicative of the most intense suffering. Upon examination I found the whole right flank flat, hard, and board-like to the touch, intense pain being caused by the slightest pressure. McBurney's tender point was strikingly observable in this case, which, together with the fever and constipation, justified me in the diagnosis of appendicitis. I placed my patient on the same treatment employed in the above case, with the exception of larger doses of morphine. Under the treatment employed the severe symptoms rapidly subsided, and the patient became convalescent on the sixth day; but being a little refractory and disobedient to instructions, he suffered a relapse, which, I am happy to say, was satisfactorily and easily controlled, and he is now quite well and at his usual post of business.

These two cases, which are typical of the disease under consideration, which were attended with well-marked and grave symptoms from the outset, both of which suffered severe relapse with augmentation of all the threatening symptoms usually observed, and finally their complete recovery under the medicinal treatment outlined above, is a sufficient justification to my mind for a plea for conservatism in the management of these cases, and no less warrants us in condemning the too frequent resort to an operation which is necessarily surrounded by dangers, numerous and grave, and which often proves fatal in its results.

A Greek Medical Work Two Thousand Years Old.—Mr. F. G. Kenyon, who last year edited the newly discovered papyri of Aristotle and Herondas, describes another similar manuscript which contains an ancient treatise upon Medicine by a Greek author, probably of Alexandria. It was written about 100 B.C.

SPINA BIFIDA—EXCISION—RECOVERY.

By F. J. GRONER, M.D.,

GRAND RAPIDS, MICH.

SURGEON TO THE U. B. A. HOSPITAL, CONSULTING SURGEON TO ST. MARK'S HOSPITAL, AND TO MERCY HOSPITAL.

In the tabulated report of thirty-four cases of spina bifida treated by excision, as given by Dr. C. A. Powers in the MEDICAL RECORD for July 16, 1892, I see notice of a case operated on by myself in 1888 and reported in the American *Lancet* of the same year. The case is now in perfect health. I wish to add another case to the list.

On September 10, 1890, I went to Big Rapids, Mich., and, with the assistance of Dr. Dodge, operated on a child of C. Russell, of Deer Lake, aged seven months. The tumor was small at birth and had gradually increased until at the time of operation it was the size of an adult's closed fist. It was in the lumbar region of the spine and caused a great deal of nervous irritation. Chloroform was the anæsthetic used. Dissection was carried down to the base of the tumor, which was transfixed, tied, and cut off. Leakage occurred; to stop this I passed a hare-lip pin through the stump and applied the figure-of-eight suture. The integument was drawn firmly over the pedicle, and the head of the pin was allowed to protrude from the wound. The pin was removed in forty-eight hours. There was not primary union of the wound, but the child made an uninterrupted recovery. On July 4, 1892, the father reports the child "fat and perfectly healthy."

Both were cases of meningocele.

July 23, 1892.

EXTRACTION OF A SAFETY-PIN FROM THE LARYNX WITH MACKENZIE'S FORCEPS.

By FRANCIS L. PARKER, M.D.,

CHARLESTON, S. C.

On the evening of December 14, 1891, J. W. E——, aged five years, accidentally swallowed an open safety-pin. The pin entered the larynx, and for a time caused the most alarming symptoms of asphyxia. Death seemed imminent for one or two hours. A physician was hastily summoned, and gave an emetic, which acted without bringing away the pin. Loss of voice, with great hoarseness, followed. The boy slept well that night, and the next day was not in much pain. He could drink milk and eat soft hominy.

On the 16th, at 9 A.M., he reported at my office with his father, who gave the above history. At this time there was loss of voice, stridulous breathing, and though the expression of the face was anxious, the boy seemed comfortable.

Cocaine was applied, but the lad was so unmanageable no satisfactory examination could be made with the laryngoscope. Having just breakfasted, chloroform, with a view to further examination, at the time was deemed unadvisable, and he was told to report at 2 P.M.

On returning he was chloroformed in his father's lap, a mouth-gag applied, and with the finger I detected a foreign body in the larynx, thought to be a safety-pin. With one of Mackenzie's forceps the twirled end of the pin was seized, but there was such resistance in trying to withdraw it and such suffocation, that I was obliged to let go.

A respite was given and the foreign body was seized a second time, and turned in a different direction, but it was firmly fixed and the extraction was again a failure. The symptoms of suffocation at this period were such that preparations were made to perform laryngotomy or tracheotomy.

However, on the third trial, after seizing the foreign body, the direction of the traction was changed, and I succeeded in removing a medium-sized safety-pin one inch in length.

The next day the patient returned home and gradually regained his voice, without any complication, in about a month.

It is impossible to state positively the exact position which this open safety-pin occupied in the larynx, but judging from the force used in the first two trials to remove it by the mouth, and from the direction of the traction used in the third and successful effort, and from experiments made by placing the open pin in the larynx of a subject in the position I thought it must have been fixed, my conclusion was this: As the boy swallowed the open safety-pin, the projecting point passed under the left vocal cord and hooked under it. My failure to remove it on the first and second trials was due to the peculiar nature of the foreign body, and also to the position it occupied in the larynx, so that it could only be withdrawn in one direction. This line of traction I fortunately hit on the third attempt, thus saving the lad from the operation of laryngotomy.

TREATMENT OF FRACTURE OF THE CLAVICLE.

By A. S. KINNAMAN, M.D.,

CLEVELAND, O.

With the exception of the femur, there is no fracture with which the surgeon has to do where shortening so uniformly results as in that of the clavicle. The testimony of surgeons, from Hippocrates to the present time, is that, however careful the treatment of this fracture, deformity almost always results. The difficulty does not lie in the reduction of the fracture, for as a rule this is very easily accomplished; the trouble is to retain the reduction sufficiently long for nature to establish an osseous union. Even after the parts are properly adjusted the slightest movement of the head or arm, or even that occasioned by respiration, is frequently sufficient to displace the fragments.

I should like to call the attention of the profession to a method of treatment that has proved successful, viz., the use of the bone dowel or peg.

After reducing the fracture in the usual manner, pierce the clavicle with an awl, let it extend from one broken fragment to the other, then insert the antiseptic bone peg completely. The elbow is now suspended in a sling and the arm is confined to the chest either by a few turns of a bandage or a few broad strips of adhesive plaster.

By this method you will not encounter the difficulties met with in the wire suture advocated by Von Langenbeck, and the results will be more perfect.

A CASE OF AMPUTATION OF THE THIGH FOR TUBERCULOSIS OF THE TIBIA—RECOVERY.

By JAMES KENNEDY, M.D.,

SAN ANTONIO, TEX.

Inasmuch as operations for tuberculous disease of bone and joint structures are common, and recoveries from the same are by no means infrequent, and as I have nothing new to advance either as regards diagnosis or treatment, and no improvements to offer on the technique of surgical interference, it may seem a wanton waste of time and space to record this case. Nevertheless, I have the temerity to hope that my report may not be entirely devoid of interest or usefulness.

I was called during the third week of the patient's confinement to bed, and learned that he had been under the care of another physician for more than two weeks, and that, pursuant to his instructions, the limb had been repeatedly painted with the tinctures of iodine and iron, but without relief or benefit.

The only facts relative to the history of the case that I could elicit at that time are as follows: The boy, aged eleven, was said to have enjoyed good health from birth up to the time of his taking to bed on account of a fall which he received while playing football. He fell upon his right elbow and knee. The epidermis was denuded

from the elbow, but the knee showed no external marks of violence. He complained of a general soreness which was in all probability due to the violence, and felt feverish and ill. Pain in the knee-joint became severe, and the limb from the pedal extremity to a short distance above the joint became very much swollen. Fever was more or less continuous, according to the mother's statement, and the bowels were constipated.

At the time I first saw the patient I noted the following symptoms: He was very much emaciated. Temperature, 101° F.; pulse, 130; tongue furred, and bowels constipated. The leg and foot were very much swollen, the swelling extending to the knee-joint and very painful, particularly on pressure. The limb had a boggy feel, and the skin was tense and shiny. Fluctuation was detected with great facility, and pus was pronounced present. The patient was anæsthetized, and three large incisions were made at different points, which immediately gave exit to about three pints of pus. The abscess cavities were flushed with bichloride of mercury solution 1 to 2,000, and drainage maintained with daily flushings of the wounds. The swelling below the joint subsided, and apparent improvement followed. In a short time the pain increased and swelling occurred at and above the joint. Free incision with evacuation of a further quantity of pus, drainage, and flushing were again practised. And again improvement followed. But in the meantime the wound made over the external aspect of the tibia kept discharging pus freely, as much as three or four ounces daily, and another abscess above the knee poured out through an incision almost an equal quantity.

The amount of pus discharged seemed to be steadily increasing, and no improvement in the patient's nutrition was perceptible. Therefore I deemed it expedient to cut down upon the diseased part and remove as much of the bone as might be found to be dead, and, if necessary, make an exsection of the knee-joint.

I had no idea that the bone was so extensively diseased as I found it to be, nor did I anticipate that so radical an operation as amputation of the limb would be required.[1] Having made an incision over the anterior border of the tibia, the bone was exposed and found to be necrosed over its entire circumference. Extending my incision to the lower border of the patella, I found that the head of the tibia had been almost entirely destroyed. The bone was extensively involved in the tuberculous process, and throughout its upper half its ravages were very marked. I opened the joint and found the articular surface of the femur apparently sound, and but for the soft parts being badly diseased, I would have amputated at the knee-joint. As it was, we were compelled to go three inches above the joint in order to find material for sound flaps.

The operation was practically bloodless (thanks to Esmarch and fortunately for the patient), and was performed with the usual antiseptic precautions. The dressings were not disturbed until the sixth day. There was very little pus at any time, and the temperature fluctuated between normal and 101° F., but rarely rising above 99° F.

The patient's condition began to improve almost from the very moment of the operation, and passed on to a recovery which was both rapid and satisfactory. On the fourteenth day he was able to walk about the room on crutches without discomfort. Since his recovery he has added some important features to the history of the case. He tells me that the limb had given him trouble at intervals for a year previous to the operation. "Often while running he would be suddenly seized with pain in the knee, and sometimes it would be so severe as to cause him to fall to the ground. The pain would soon pass off and leave him comfortable for a long time. After running about all day he would sometimes suffer at night from pain in the knee-joint, and at one time he was laid up for two weeks with it. He never noticed any swelling in the joint, although it might have been present."

There seems to be no doubt that disease was present in the bone for some time (a year probably) previous to his late accident, probably in a subacute or chronic form, occasioning the patient but very little trouble until an acute process was lighted up by the injury.

Judging from the appearance of the bone, I am inclined to believe that the disease existed first in the diaphysis of the tibia, and extended centrally and upward through the epiphysis into the joint, destroying the interarticular cartilage, but not affecting the semilunar cartilages or the upper circumference of the epiphysis, with the exception of its anterior and posterior aspects.

The upper epiphysis and the diaphysis (what remains of them) were completely separated by the ravages of this disease, the bone being eaten away through its entire thickness, and were held in approximation by the fibula, whose articulations with the tibia I left undisturbed and for this purpose.

[1] Although dead bone was discovered at the time incision was first resorted to, it was decided to defer an operation for its removal until such time as the patient's general condition had improved, he being very much emaciated and enfeebled by his suffering and disease.

A CASE OF CHOREA IN A NEGRO.

By PHILIP S. ROY, M.D.,

WASHINGTON, D. C.

In an article on chorea by Allan McLane Hamilton, written in 1886 for "The Reference Handbook of the Medical Sciences," I find he states that Dr. Mitchell has found, after careful inquiries, that chorea is unknown in the negro race. Probably no neurologist in this country has had the opportunity, personally, to carefully study nervous diseases in the negro, and this explains why so many incorrect statements are made.

Not ten years ago W. A. Hammond wrote, in his work on nervous diseases, that hysteria did not occur in the negro. I believe I was among the first to refute this statement in an article published in your journal, about four years ago. Certainly, from a scientific point of view, it is interesting to study diseases in the lower races, just as we compare our anatomy, physiology, and diseases with those of the lower animals.

The case of chorea I now have under observation is in a full-blooded negro child, seven years of age. Since writing the above, Dr. Irving C. Rosse, the neurologist, has kindly seen the case with me and confirmed my diagnosis. It is a very marked case.

The Manufacture of Freaks.—Victor Hugo says ("L'Homme qui Rit"), anent a sect that practised very sinister prosthetic surgery: "The 'comprachicos' were a bizarrely hideous, nomad association famous in the seventeenth century, forgotten in the eighteenth, and unknown to-day. They were honest men. They opened a door, entered, bargained for a child, paid and carried it away. The comprachicos were Christians and even good Christians, as befits an association which had its origin in pious Spain." Commenting on this statement the *Medical Standard* some years ago (vol. viii. p. 123) said: "The artificial manufacture of 'freaks' by these procedures, however, lasted much longer than Victor Hugo indicates in his quasi-historical remarks. In the early part of the present century, a Dr. Harper was detected in England in the manufacture of 'freaks' for the English and continental market (*Chicago Medical Review*, vol. iii). He twisted a child's head in an apparatus devised by himself, so that it would look permanently over one shoulder. He grafted a rat's tail on a child's nose. He manufactured 'double monsters' by removing from the backs of two children slips of flesh and allowing the wounds to cicatrize together. After the children recovered, they were taught music, dancing, French, and Italian. He was particularly strict about their observance of the Sabbath. He had a regular catalogue of prices to showmen, who were allowed a discount when the subject was furnished."

Progress of Medical Science.

Resection of the Sternum.—Dr. Yvert reports the case of a soldier, aged twenty-one, who, in addition to general bronchitis, had cold abscesses in the wrist and foot, and one over the manubrium of the sternum. On opening the latter collection the upper part of the sternum was found bare, carious, and covered with fungosities; the body of the bone was displaced so as to lie in front of the manubrium, and the third chondrosternal articulation was disorganized, while behind the sternum there was a vast purulent collection. Four centimetres of the body of the sternum were resected, free drainage provided for, and the parts immobilized with diachylon plaster. The patient left the hospital in eighteen days with only a small fistula, which closed spontaneously after three months. Two months later the man was fit for service. —*British Med. Journal, Sup.*, May 14, 1892.

Pregnancy with Ovarian Tumor.—Dr. Gardner (*The Montreal Medical Journal*, February, 1892), in report of four cases of pregnancy complicated by ovarian tumor, in which three successful ovariotomies were performed, advances the following conclusions: 1. The association of pregnancy and ovarian tumor, if left to nature, is fraught with danger to the woman, whether the termination be premature or at full term. 2. When left to nature, abortion or premature labor may occur, in either case with frequently fatal result to the mother. 3. When the case proceeds to labor at full term, the result to the mother may be rupture or such other injury to the tumor that fatal peritonitis carries her off. 4. Tapping of the tumor, while it may temporarily relieve tension, is by no means free from danger by injury to the uterus or otherwise, and it does not cure the patient. 5. Ovariotomy with modern precautions is nearly as safe in the non gravid condition of the uterus, while the woman is at once cured of a disease which must ultimately demand operation. 6. Serious complications, such as torsion of the pedicle and consequent peritonitis with adhesions, necessitating the use of the drainage-tube for so long a period as five days, does not necessarily lead to abortion. 7. Ovariotomy in the present status of surgery, in the great majority of cases, must be the only proper treatment, and is often urgently demanded to relieve tension. 8. The indication for the operation in the case of small abdominal tumors is even more urgent, because of their great liability to torsion of the pedicle; and in the case of pelvic tumors, by reason of the almost certain rupture or necrosis from compression during labor.

Ingals on Diphtheria.—At the annual meeting of the Illinois State Medical Society, held at Vandalia, May 1892, Dr. E. Fletcher Ingals read a paper on "Diphtheria," of which the following is an abstract: It is a constitutional disease with local manifestations, being similar to vaccinia, the false membrane formed in the fauces being analogous to the peculiar vesicle developed after inoculation with vaccine virus. The disease is contagious, and probably due to a specific micro-organism. Its identity has not, however, been fully established. The Klebs-Löffler bacillus is most generally accepted. Numerous clinical observations and experiments, however, have demonstrated that pseudo-membranous inflammation is often produced without this bacillus, as, for example, that resulting from injuries to the throat or various chemical caustics; certain exudative inflammations, as those attending measles and scarlet fever are not attended by the Klebs-Löffler bacillus. These latter inflammations have been termed pseudo-diphtheria, and it is stated that they can only be distinguished from true diphtheria by the absence of the Klebs-Löffler bacillus, by their being followed by paralysis, and by not being attended by a peculiar form of albuminuria which occurs in true diphtheria independently of dropsy or uræmic poisoning. The necessity for assuming that there are two varieties of diphtheria seems to justify the conclusion that the identity of the micro-organism which is supposed to cause the disease is as yet uncertain. Primary inflammation of the fauces apparently greatly favors the development of diphtheria, and its development and progress seem to be largely influenced by bad hygienic surroundings, such as impure drinking-water, sewer-gas, and the emanations from decaying vegetables and unclean cellars; but it is doubtful whether any of these conditions can of themselves produce the disease. The most frequently predisposing cause of diphtheria is exposure to cold. A careful and detailed description of the symptoms was given, after which the prognosis was discussed at length. It is always grave, and the patient can never be considered out of danger until he has been well three or four weeks, because of the serious sequelæ which sometimes follow. Death may come on within a few hours, but not usually before the fourth or fifth day. The mortality varies according to the severity of the epidemics. The deposit of false membrane in the nose, or nasopharynx, or intestines; the occurrence of extreme pain in the ears or throat, of purpuric spots upon the skin, or of epistaxis or other hemorrhages, and the presence of persistent anorexia, vomiting, diarrhœa, or suppression of urine, are all indications of grave import. Patients may die slowly from asthenia or more quickly by suffocation, or they may suddenly be carried off by heart-failure or convulsions. Not infrequently paralytic symptoms follow the attack about the third week, but except in cases where the respiration or circulatory centres are involved, recovery usually occurs, though it may be delayed for weeks, or even months, and sometimes the paralysis is only partially recovered from, more or less loss of muscular mobility remaining.

For treatment an endless variety of drugs is used. Of first importance is isolation, removal of unnecessary furniture from the sick-room, which must be well ventilated and the door hung with sheets moistened with antiseptics. Ice may be given freely by the mouth, and ice-bags or the ice-water coil should be applied to the throat. If this causes pain, hot applications may be used, and the latter are preferable after the membrane begins to separate. Liquid nourishment should be given frequently and in large quantities. Alcoholic stimulants should not be used early, but kept until depression supervenes. Steam impregnated with lime-water can be used, but is of doubtful utility. Lactic acid, medicinal solvents, tannic acid, and similar astringents are popular, but of little use. Antiseptic solutions, such as of bichloride of mercury, carbolic acid, potassium permanganate, chlorinated soda, chloral, sulphurous acid, and peroxide of hydrogen are useful; also tincture of myrrh, alcohol, tincture of chloride of iron, tincture of iodine, and strong solution of nitrate of silver. The author uses tincture of chloride of iron in large doses, about one minim for each year of the child's age, combined with glycerine and sirup of tolu. This is given every hour or two. Between doses he uses as a gargle or spray a saturated solution of boric acid in cinnamon water, which is harmless and apparently very beneficial. He gives quinine, and when depression comes on alcohol in some form, and nux vomica frequently and in large doses till constitutional effects are observed. He also in some cases uses large doses of calomel till catharsis is obtained, but does not favor the stronger preparation. When the disease extends to the larynx, mild emetics can be given, and also calomel to catharsis. The speaker advised the use of O'Dwyer's tubes early, and then if necessary trachectomy can be performed later.

Doctors of Philosophy, not Medicine.—The quotation, "Who shall decide when doctors disagree, and soundest casuists doubt like you and me?" was written by Alexander Pope, "Moral Essays," Epistle 3, line 1. The original did not apply to doctors of medicine, but to doctors of philosophy.—*Journal of American Medical Association.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, August 20, 1892.

THE INSANITARY CONDITION OF CHICAGO.

WE have adverted more than once to the high rate of mortality from typhoid fever in Chicago, and to the apparent indifference of the denizens of that place to the existing evil. Other journals have also called attention to the condition of the city, and various articles have appeared recently on the same subject. Among these one by Professor William T. Sedgwick and Mr. Allen Hazen, on "Typhoid Fever in Chicago" (*Engineering News*) has attracted justly much attention, especially outside of that city.

These gentlemen have studied carefully the history of typhoid fever in Chicago, and have made some investigations as to the cause of the extreme prevalence of the disease there.

It is estimated that over 20,000 cases of typhoid fever occurred in Chicago in the year 1891. The total number of fatal cases was 1,997. These figures mean that over one per cent., or about one person in every 60, was stricken down with a preventable disease last year. Such facts are most extraordinary; for they cannot be paralleled by any other great city in the civilized world. They are an evidence of gross neglect or barbaric ignorance; and they constitute a menace to visitors in the future that cannot be too seriously regarded. Typhoid fever practically only attacks persons between the ages of ten and thirty. Of every hundred persons between these ages in Chicago last year, it is safe to say that two had typhoid fever.

That these statements are not exaggerations is shown by the following table, which gives the population and the number of deaths from typhoid fever in the cities and States named:

	Population (in round numbers).	Deaths from Typhoid Fever.
Baltimore, 1891	455,000	140
Boston, 1891	459,000	154
Cincinnati, 1891	300,000	186
New York City, 1888	1,536,000	364
" " " 1889	1,583,000	397
" " " 1890	1,631,000	352
" " " 1891	1,700,000	384
Philadelphia, 1891	1,092,000	684
State of Massachusetts, 1890	2,239,000	835
London, England, 1890	4,421,000	619
State of New York, 1890	6,000,000	1,612
Chicago, 1891	1,200,000	1,997
Baltimore, Boston, and Cincinnati, 1891	1,214,000	480

Chicago, with almost exactly the same population, had in 1891 more than four times as many deaths from typhoid fever as Baltimore, Boston, and Cincinnati combined.

Since 1880 Chicago's typhoid fever-rate has been higher than that of any other of our large cities, although at times Philadelphia has been a close rival.

The cause of Chicago's unenviable eminence as a great typhoid-fever centre is believed to be the deficiencies in its systems of sewerage and water-supply. The pumping-works which ought to lift and direct the flow of the city's waste toward the Mississippi and the little town of St. Louis thereon, are insufficient, and the sewage pours into the lake and pollutes the water-supply. We believe that attempts are being actively made to remedy this. Meanwhile it is currently stated that the medical men of the town are desired to be a little careful about how they report typhoid fever. Whether this be so or not, the number of deaths reported for May was 70, which is at the rate of 800 a year—an average which still gives Chicago a supremacy that the city seems to enjoy, judging from the following item clipped from *The Medical Recorder*:

"The Practitioners' Club held their ninth banquet, and the last one for the season, at the Leland Hotel, May 30th, under the graceful presidency of Dr. Fernand Henrotin. The subject for consideration after the dinner was 'The Sanitary Drainage of Chicago.' Members of the Drainage Board were present, and in a clear and instructive manner explained the present situation, what had to be accomplished, the difficulties in the way, and the steps already taken to surmount them. . . . It was one of the pleasantest and most interesting of these enjoyable meetings."

And seven hundred new cases of typhoid fever the same month!

FEMALE PHYSICIANS AND THE ASYLUMS.

IN Virginia the proposed legislation requiring that there shall be one female assistant at each of the hospitals for the insane has failed. Its friends hope for better luck next time. Meanwhile the Pennsylvania Medical Society has taken a vote and adopted the following:

"*Whereas*, The Medical Societies of the counties of Berks, Bucks, Bedford, Lehigh, Lycoming, Mifflin, Northampton, Montgomery, Schuylkill, Somerset, Perry, and Westmoreland, and perhaps others not yet heard from, have passed resolutions in favor of conferring the entire control and management of our hospitals for the care of the insane on the Boards of Trustees of these institutions, now under the care of superintendents, and of making it incumbent on them to appoint women physicians to have the medical care of the insane of their sex; and,

"*Whereas*, This Society at its meeting in Pittsburg, in 1890, passed a resolution in favor of the reforms advocated by the County Societies above named; and,

"*Whereas*, The marked success of management by trustees in the Eastern Hospital at Norristown, and the value of female physicians for the female insane have been exemplified grandly in that place, with its 2,000 patients; therefore,

"*Resolved*, That a committee be appointed by the President of this Society to memorialize the Legislature for the enactment of laws to carry these reforms into effect."

As a matter of fact, the latter part of the above resolutions is pure rhetoric. The attachment of a female physician to the Norristown Asylum has brought to that institution neither "grand success" nor the opposite. It has made very little, if any, effect upon the economics of asylum administration or the therapeutics of asylum treatment. The truth is, that those physicians best acquainted with the management of asylums do not, as a rule, favor the legal establishment of medical women on the staff. Perhaps they are prejudiced; but it is fair to assume that they know their business better than the professional world-betterers who are bolstering up the movement for compulsory female medical attendance on the insane.

We believe it should be made an optional matter with the superintendent. Sometimes a female physician is needed and is useful, sometimes she may be useful but not needed, and there are specimens of the lady medical who neither adorn nor help this ill-illumined world. It is wrong in principle and unwise in practice to legislate physicians into office because of their sex. The world is governed too much when such laws are enacted.

THE KEELEY CURE IN LONDON.

Our medical colleagues of England have taken the Keeley cure more seriously than have American physicians. They have gone to the trouble of holding meetings, making analyses, and passing denunciatory resolutions. Perhaps this is the best way to attack a humbug, after all, though it makes life a little more restless for honest people. The Society for the Study of Inebriety has particularly looked after Dr. Keeley on his recent trip abroad. They managed to snatch from him the protection of the Church, and they have held a meeting calculated to throw much interesting light on the methods of gold-curing.

A competent analyst, who subjected the curative fluid to examination, reported that he found neither gold nor chlorides. What he did find present was: Water, 61.31 per cent.; sugar, six per cent.; a small quantity of mineral salts, principally lime, probably from herbs; and 27.55 per cent. of pure alcohol.

An Australian physician, Dr. Usher, gave a description of his visit to the sanitarium at Dwight. "The medical staff," he said, "consisted of unsuccessful practitioners, who were paid from $3,000 to $7,000 a year, and they did all the work." One of the staff took Dr. Usher to where three rows of men were being injected in the left arm with five drops out of a little porcelain bowl containing a pinkish material—atropine really. Four of the patients wore glasses, and they told him that they could not see three or four days after the treatment, and became blind weeks together. Seventy per cent. of the patients had glasses. They suffered, too, from giddiness. One patient had been at the institution nine weeks, he said, and was afraid to leave because three of his "pals," who had left ten days before, got drunk, and had to come back. Another patient remained because, he said, if he stayed there two or three months an aunt had promised him an annuity, and he "wanted to see the time out." There was a "Bichloride of Gold Club" in which there were "graduates" and "undergraduates," so called. They did not appear to be healthy; some of them seemed to be under the influence of some drug—apparently atropine. "About £40,000 a year was spent in advertising or in subsidizing people to advertise the concern, which was now engineered by some of the "smartest" men in America. The thing was most lucrative. Two bottles of the preparation cost 36 shillings. Every man who went to Dwight had to pay $25 down and from $5 to $25 a week; and all this money flowed into the coffers of the company.

After such descriptions as this it is not to be wondered at that the Society for the Study of Inebriety passed the following resolutions:

"That this meeting of the Society for the Study of Inebriety (of which the members are registered British medical practitioners) is of opinion that any so-called 'cures' for inebriety, the composition of which is not disclosed, are unfit to be commended by honorable members of the medical profession, who are bound to place the full details of their treatment before their professional colleagues—a requirement as essential in the interest of the public as it is consonant with the disinterested practice of scientific therapeutics.

"That this meeting, having been informed by a competent London analyst, who has made a special analysis, that the alleged 'bichloride of gold cure' shows no trace of gold or of chlorides, and contains 27.55 per cent. of alcohol, condemns unreservedly the prescription of such an intoxicating preparation to an inebriate."

DOES THE BLOOD ROTATE?

The earth is said to be shrinking, but the imagination of certain scientific medical men cannot be withered by age or contracted by the change of years. A San Francisco physician who has evidently a fine play of fancy, and a considerable aptitude for mechanics, has put forth the theory that the blood, as it circulates in the arteries, has a rotary motion and a centrifugal force. He thinks he has succeeded in proving that, "just as the earth rotates on its axis while moving through space, so the blood rotates on its axis while moving through the arteries; that this rotary movement of the blood, with its consequent centrifugal power, is absolutely necessary and indispensable to health and life; that with the existing circulatory system none but a rotary moving current is possible."

Now, perhaps the doctor is right in all this, and perhaps he is not. An excellent authority has demonstrated that the penis is rifled and that the urinary stream rotates, or would do so, if the bladder were strong and the urethra long enough. If the urine rotates, why not the blood?

We only object to the San Francisco thesis on the ground that the author has done everything but proved it. Now, the proof could not be very difficult, as the poet of the rotary theory admits, and it would only have been fair to himself and science to have waited a few days and tested his centrifugal force before enunciating its existence. Arteries have been tapped and the circulation studied from the time of Galen; and if there is really a rotation which has never been observed until the year 1892, in San Francisco, the world would be pleased to know it.

News of the Week.

Dr. William A. Smith, one of the oldest physicians in Newark, died recently after a long illness. He was born at Guilford, Chenango County, N. Y., on March 30, 1820, and was graduated in 1847 from Geneva College.

Sterilized Milk for the Poor of Boston.—The sum of $500 a month during the hot season has been given by two persons, to distribute sterilized milk from the Walker-Gordon Laboratory among the poor of the city in cases of gastro-intestinal diseases of infants. The distribution is to be made through the physicians of the Boston Dispensary and the agents of the Society for the Prevention of Cruelty to Children. More contributions for this object are needed.

Marble Swallowing.—A promising lad was brought to the Cardiff Infirmary not long ago to be relieved of fifty-three marbles which he had swallowed "for keeps." Mr. J. Thomas, who relates the case in *The Lancet*, is responsible for the statement that when the boy was inverted and shaken, "the rattling as of a receding wave on a pebbly beach could be heard for yards around." The marbles were all passed in single file per anum, at intervals, during the succeeding forty-eight hours. Most of them were "commeys," but there were two valuable "blood alleys" and one priceless "buck."

Dr. Enrico Tanfani, a promising young physician of Florence, recently died in consequence of a fencing wound. His antagonist did not notice that his foil had lost its button, and making a lunge with it, drove it into Dr. Tanfani's breast.

Suicides in Berlin.—The suicidal impulse seems to be endemic in Berlin, and lately there has been a remarkable increase in the number of self-killers, no less than twenty-two having been reported for the week ending August 13th. In many cases the reason for the suicide was most trivial, although in the greater number the usual lovers' quarrel was the cause. One man was driven to self-destruction through remorse for having broken his antagonist's clavicle in a fight.

Yellow Fever at Tampa.—It was reported in the daily press a few days ago that yellow fever had appeared at Tampa, Fla., but this is now contradicted. A vessel arrived with yellow fever aboard, but she was anchored some distance away and no communication with the shore was permitted.

Glanders Among Car-horses.—A number of cases of glanders were recently discovered in one of the city car-stables, by the veterinary surgeon of the Board of Health. All the diseased animals were killed, and the Society for the Prevention of Cruelty to Animals has begun a prosecution against the stable foreman who sent the sick animals out, and against a driver who drove one of them.

Small-pox is reported from many ports of the country, but nowhere in a really epidemic form, excepting possibly at a small town in Georgia, where about one hundred cases occurred. The health officers, however, soon succeeded in wiping out the disease. In this city a number of cases have been reported from time to time in different neighborhoods, showing that there must have been several centres for its spread. Several cases which had been concealed for some time have also been discovered. The Board of Health inspectors are now making a house-to-house visitation of the entire tenement-house region, in order to ferret out any other cases which the friends may be trying to conceal. There have been about two hundred and fifty cases here since the beginning of the year.

A Cholera Scare in New Jersey.—The city of New Brunswick, N. J., was, alarmed about a week ago by a report that cholera had appeared at Helmitta, some fifteen miles distant. This is a small manufacturing village, and many Russians and Poles are employed in the factories. The report proved to be untrue, however, as the disease was found to be a severe form of dysentery, and not cholera.

A Testimonial to Sir George Buchanan, F.R.S.—It has been proposed to open a subscription list in England with a view of presenting to Sir George Buchanan, who has lately resigned the post of Medical Officer of the Local Government Board, some testimonial in recognition of his services in the cause of preventive medicine. It has been suggested that sanitarians in this country might also wish to subscribe to this testimonial. Any so desiring may send their contributions to Dr. John S. Billings, Army Medical Museum and Library, Washington, D. C., who has been authorized to collect funds for the purpose in the United States.

Vaccination against Cholera.—Dr. Hafkin claims to have elaborated a vaccine capable of conferring immunity against the disease in animals. He has also vaccinated a number of his medical colleagues, and reports the results in the *Bulletin Médical* of July 31, 1892. In each case he noted fever, malaise, and loss of appetite for a few days succeeding the injection. He did not carry his experiments so far as to feed his friends upon comma bacilli, in order to prove protective the efficacy of his vaccine. He says, however, that this has been abundantly demonstrated in the case of animals, and his experiments upon man have shown that there is not the slightest danger to be apprehended from the inoculations. But Ferrán will doubtless dispute Hafkin's title to priority in cholera vaccinations.

Dr. J. Albert Kimball, a dentist of this city, killed himself in his office on the morning of August 16th, while suffering from melancholia.

Sulphuric Acid Instead of Wine.—The pastor of a Presbyterian church in Dutchess County, N. Y., in giving the communion to his congregation last Sunday morning, accidentally substituted a bottle of dilute sulphuric acid for the wine. About twenty persons sipped the acid, without any serious ill effects, although they were greatly alarmed when the mistake was discovered.

The New St. Luke's Hospital.—The competitive plans for the new building of St. Luke's Hospital were recently placed on exhibition in this city. Ten architects have offered plans in response to an invitation sent them some time since. The hospital authorities do not seem to favor the pavilion system, as nearly all the designs submitted are for a four-story building with basement and attic.

Smuggling Antipyrin.—The captain of the British steamship Rhein, from Bremen, was arrested in New Orleans a few days ago for smuggling antipyrin. The Treasury authorities in Washington have been aware for some time that a large smuggling business was being done in this particular drug, for the reason that large quantities of it have been sold at a price below that charged by the single house which imports it into this country. The Government detectives have been on the watch for the smuggler for some time, and finally arrested the captain of the Rhein, who confessed that he had been bringing in the drug surreptitiously, and had made a fair profit in so doing.

"**The Medical Recorder**," of London, has recently come to an end. It was a well-conducted paper, and most of its selections were made with judgment, but unfortunately people didn't want it enough to pay the subscription price.

Medical Politicians.—Members of the profession in England seem to take a more active interest in politics than those in our country. A large number of medical men were candidates during the recent parliamentary elections, not a few of them succeeding in winning the prize. A surgeon in Southampton took such a decided interest in the contest that he killed a man whose political views did not coincide with his own.

Mr. Conan Doyle, the novelist, is a doctor of medicine, and was for a number of years ship's surgeon on British vessels. He has dropped his title since retiring from practice. It is a pity that he changed his profession, for good ship's surgeons are more needed, as well as more rare, than good novelists.

The New Russian Pharmacopœia has recently been issued. Compared with the preceding work, it contains a smaller number of articles, three hundred and eighteen having been discarded, while only one hundred new ones have been added. The total number now officially recognized is eight hundred and eight.

Dr. Thomas M. Healey died on August 10th, at his home in Cumberland, Md., at the age of fifty-three. Himself the son of a physician, he early developed an aptitude for that calling, and during the thirty years of his medical life he gave ample proof that he had not mistaken his vocation. He was a skilful diagnostician, a more than usually successful therapeutist, and a ready writer on medical subjects.

The Cholera has made little or no advance toward Western Europe during the past week, and is reported to be on the decrease in St. Petersburg. It appears that the disease in Russia has been of a more severe type than the authorities were at first willing to admit, the official report recently published showing that the mortality-rate in the more seriously infected districts was about fifty per cent. of those attacked. The daily average of cases during July was, for all Russia, 8,601, and the number of deaths per day was 4,268. Our Government is said to be considering the expediency of prohibiting altogether the importation of rags and paper stock from Europe and the East as long as the cholera is epidemic.

Medical Society of Virginia.—The Twenty-third Annual Meeting of this Society will be held at Alleghany Springs, September 13th, 14th, 15th, and 16th. The object for general discussion will be "Vertigo." The discussion will be opened by Dr. E. T. Brady, of Marion, and continued by Dr. L. C. Gray, of New York. The following papers are announced: "Appendicitis," by Dr. William Edward McGuire, of Richmond, Va.; "Laparotomy and the Good Accomplished by It in Gynecology," by Dr. R. S. Martin, of Stuart, Va.; "Some New Ideas that are Old," by Dr. S. W. Dickinson, of Marion, Va.; "Necessity of Prompt Action in Cases of Placenta Prævia, with Report of Cases," by Dr. L. H. Keller, of Luray, Va.; "Some Ocular Diseases in Children," by Dr. Philip Taylor, of Richmond, Va.; "Mysteries of Medicine," by Dr. C. W. Gleaves, of Wytheville, Va.; "Injuries of the Knee: Their Treatment and Results, with Special Reference to the Prevention and Cure of Suppurative Action in and about the Joint," by Dr. M. W. O'Brien, of Alexandria, Va.; "The Causative Relations of Bacteria to Disease," by Dr. C. M. Blackford, of Lynchburg, Va.; "Common-Sense in the Treatment of Discharge from the Ear," by Dr. Alexander Duane, of New York, N. Y.; "Some Uses of the Iodides," by Dr. L. G. Pedigo, of Roanoke, Va.; "Cataract," by Dr. Joseph A. White, of Richmond, Va.; "Some Remarks on the Continued Administration of Digitalis, Illustrated by the Report of a Case," by Dr. F. M. Brooks, of Fairfax Station, Va.; "Uterine Hemorrhage and Present Method of Treatment," by Dr. A. Vander Veer, of Albany, N. Y.; "Surgical Management of Fibroid Tumors of the Uterus," by Dr. Joseph Price, of Philadelphia, Pa.; "Modern Electrical Methods as a Substitute for Surgery in Certain Pelvic Affections," by Dr. G. Betton Massey, of Philadelphia, Pa.; "Sexual Hypochondriasis and Perversions of the Genesic Instinct," by Dr. Irving C. Rosse, of Washington, D. C.; "What shall be Done with the Imbecile?" by Dr. Samuel J. Fort, of Ellicott City, Md.; "Hypnotism as a Therapeutic Agent," by Dr. William Lee Howard, of Baltimore, Md.

"**The Bird that Laid the Vaccination Egg**" is a virulent attack on the personal and professional character of Jenner, the discoverer of vaccination as a protection against small-pox. The gravamen of the argument is that Jenner's success, in disseminating his views were due to his being a Fellow of the Royal Society, a distinction conferred upon him—so it is alleged—as a reward for his observations on the habits of the cuckoo. These observations, it is asserted, have since been completely disproved, and as Jenner was wrong on that point, therefore he was wrong all round. The assertion is, however, false, as others have recently observed the very same habit of the young cuckoo which Jenner described.

The American Medical Association and Politics.—The editor of the *Medical Mirror* says that he wants no more of the medical politics of the American Medical Association. For years he had been a member engaged in reading papers and taking part in the discussions of the sections with no thought of office, until three years ago friends fired him into public place without consulting him; he tried to do his duty, and at the expiration of his term retired as gracefully as he could.

Reviews and Notices of Books.

Braithwaite's Retrospect. Vol. CV. January to June, 1892. London: Simpkin, Marshall & Hamilton Co. 1892.

The scope of this work is too widely known to require any extended comment. In this handy volume has been condensed the cream of English medical literature of the first half of the current year. Its index is complete, and it will form a valuable working book for any library.

Hydrotherapy at Saratoga. By J. A. Irwin, M.D., etc. New York: Cassell Publishing Co. 1892.

In successive chapters are discussed the geography and geology of Saratoga, origin of mineral waters, and analysis of the various springs. The latter part of the volume is devoted to the general therapeutics of balneology, with special reference to the local conditions at the great American spa. A judicious tone is followed throughout, and the chapters will prove interesting to anyone, physician or layman, who is intending to visit Saratoga. The work is useful, however, merely as a general guide, and will not take the place of a physician for one who visits Saratoga for health purposes.

Diseases of Women: A Treatise for the Use of Students and Practitioners. By Alexander J. C. Skene, M.D., Professor of Gynecology in the Long Island College Hospital, Brooklyn, N. Y. Second edition, revised and enlarged. New York: D. Appleton & Co. 1892.

In the present edition new chapters have been added on ectopic gestation, diseases and injuries of the ureters, vesical hernia and its surgical treatment, and the latest views of the author have been given in the discussion of laparotomy, ovaritis, and injuries of the cervix uteri and pelvic floor. The typographical appearance of the volume, together with its wealth of illustrations, are beyond criticism.

The high position justly accorded Dr. Skene in gynecology renders it superfluous to write merely formal words of commendation. Probably no book was ever written by a master-mind which did not cause more or less discussion as to the truth and logic of some of its doctrines. In just so far as a writer on medical and surgical topics incorporates his own experience into his pages, is he liable to run counter to the ideas of other men in minor matters. We take pride in regarding the present work as an able exponent of American gynecology. It bears the impress of the careful student and the able clinician.

We cannot here enter into a discussion of controverted points, wherein Dr. Skene differs from other gynecological teachers. We congratulate the author that his work has been made a text-book in so many of our leading medical schools. No one is more than he moulding the views of the present generation of American students.

The Diagnosis of Diseases of the Nervous System: A Manual for Students and Practitioners. By Christian A. Herter, M.D., Physician to the Class of Nervous Diseases, Presbyterian Hospital Dispensary. New York: G. P. Putnam's Sons. 1892.

This is a work that commends itself to the reader as one that is eminently practical and well suited to the needs of the young practitioner, or of the student attending a dispensary class on diseases of the nervous system. There are chapters on the structure and function of the nervous system, symptomatology, diagnosis of the position of the lesion (localization) and of its nature, of clinical types, and an important one on the distinction of functional and organic nervous diseases. Directions are given for the examination of the patient, and finally there are upward of a score of very instructive illustrations of diagnosis in specific cases. The book is, as it was intended by its author to be, elementary in character, and therefore somewhat too simple to meet the wants of the declared specialist in neurology, but for the ordinary practitioner and for the beginner in nervous diseases it will prove itself to be of undoubted value, and it is to the latter that we would specially commend the work.

Homœopathic Bibliography of the United States, from the Year 1825 to the Year 1891, Inclusive. Carefully Compiled and Arranged by Thomas Lindsley Bradford, M.D. Philadelphia: Boericke & Tafel. 1892.

This might have been made a very valuable work, for it seems to be very complete and is evidently the fruit of much patient labor on the part of the compiler, and furthermore the field was unoccupied. But Dr. Bradford has, for some reason, seen fit to arrange it by authors instead of by subjects, consequently the book is worthless as a work of reference. There is an index, but that is no help, for it, too, has to do only with authors. It is a pity that so much time and labor have been thrown away in making a book that is of no practical utility, when the same amount of time and labor judiciously expended might have resulted in a reference work of great historical value.

Proceedings of the Philadelphia County Medical Society. Volume XII. Session of 1891. T. B. Schneideman, M.D., Editor. Philadelphia. 1891.

This handsomely printed volume of transactions bears testimony to the fact that the work of the Philadelphia County Medical Society during 1891 was fully up to that of the preceding years. The work contains upward of sixty papers, and a note of the editor states that several papers read before the Society during the year were not printed in this volume.

Transactions of the Southern Surgical and Gynecological Association. Volume IV. Fourth Session, held at Richmond, Va., November 10, 11 and 12, 1891. Published by the Association. 1892.

The volume before us contains the usual number of papers on subjects relating to diseases of women and to general surgery. It is fully up to the average of previous volumes of the "Transactions," and bears evidence to the fact that the Society is a live one and that its members take sufficient interest in its meetings to prepare papers worth listening to and worth preserving in permanent form.

Les Maladies des Yeux dans leurs Rapports avec la Pathologie Générale. Par le Dr. Emile Berger. Leçons Recueillies par le Dr. R. de Saint-Cyr de Montlaur, Revues par le Professeur. Avec 43 Figures Intercalées dans le Texte. Paris: G. Masson. 1892.

This is an excellent treatise on diseases of the eye in their relation to general diseases. It is, of course, well known that ocular changes often accompany or follow systemic diseases, the retinal changes in Bright's disease being perhaps the most familiar to the general practitioner; but few realize how varied these changes are, and how many and different diseases they accompany. The relations here existing are often treated of at some length in ophthalmological works, but as the eye troubles are grouped under those of the lids, cornea, lachrymal apparatus, etc., the reader obtains no clear idea of the various affections that may accompany any particular pathological entity. In this book, however, the author has grouped the eye diseases according to their dependence upon the general affections, so that the reader may see at once what alterations in the different parts of the visual organs may arise from one and the same systemic disease. The work will be as useful to the general practitioner as to the ophthalmologist.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 1, 1892.

DR. GEORGE L. PEABODY, PRESIDENT, IN THE CHAIR.

Case of Huntington's Chorea.—DR. CHARLES L. DANA presented a patient suffering from Huntington's chorea. His ancestors had come from Scotland, and for four generations gave a history of chorea. His great-grandmother died of this disease, which began about the age of thirty-five; his grandmother and mother also had it at about the age of thirty-three. The patient presented was about thirty-six years of age, and had begun to show symptoms of the disease about three years ago. In some instances several members of the same generation had been its victims. Patient was well until this affection begun by causing some disturbance of speech, then came some evidence of emotional weakness, then a peculiarity of the gait, and a choreic motion of the head. The mental deterioration and choreic movements continued to increase until he had to give up work and was admitted to a hospital. The head tended to droop and moved rythmically backward and forward, especially when he was walking. There were also some ordinary choreic movements in the face and upper extremities. He ground the teeth at night. There was no lack of co-ordination.

Cases Illustrating Skin-grafting.—DR. ROBERT ABBE presented three women illustrating the value of Thiersch's method of skin-grafting. The first case was that of a middle-aged woman who was suffering from lupus exedens on the face, where it had existed about fifteen years. During this time it had been treated by different persons by various means. Of late it had extended rapidly both in area and in depth, involved the soft parts in front, above, and below the right ear, also to some extent posterior to the ear and the anterior portion of the ear itself. Dr. Abbe operated, taking out all the affected tissue and cutting well into the healthy surrounding structures, removing a part of the ear, and the cartilage within the auditory canal. Skin-grafts were then made after the method of Thiersch, obtaining them from the thigh and using only a very thin external layer. Union took place throughout, and the parts presented within three weeks a smooth, healthy surface with the usual slightly uneven and reddish appearance.

The second case was one in which, seven years ago, he had removed a fibro-sarcoma from the forearm which extended no deeper than the cellular tissue. A large, open wound was left to heal by granulation. Later he had covered it by the ordinary method of skin transplantation. Five years after this, which was recently, there had been evidence of recurrence. He took away the cicatrix and covered the open surface by Thiersch skin-grafts, all of which took and left a healthy arm inside of three weeks.

The third case occurred in a woman who over two years ago sustained an extensive burn of the forearm and wrist, nearly encircling the member up to the elbow. This large surface was covered with the Thiersch skin-grafts and in a short time presented an unbroken healthy appearance throughout. It was to be observed that although the skin-grafts were so very thin when first applied, they afterward thickened and formed a pliable integument. They would "take" on any tissue, even on bone.

Exploration of the Kidney for Renal Colic.—Dr. Abbe also presented a man who for more than four years had suffered from attacks of renal colic which during their existence kept him from work. There was some blood in the urine. The symptoms pointed to calculus in the right kidney. Three weeks ago he made Koenig's incision, a curved incision in the loin over the kidney, the horns pointing upward and forward toward the rib. It was remarkable with what ease one could reach the kidney through an opening of this form, although, as in this case, there was considerable fat and the distance down to the organ was much greater than usual. The kidney was lifted, an incision made into its greater curvature until the pelvis could be explored, and the ureter probed down to the bladder. While the bleeding was greater on cutting into the cortex of the kidney than when one entered the pelvis of the organ through the fibrous structure, yet the hemorrhage could readily be stopped by pressure, and subsequently, owing to primary union, there would be no leakage of urine. Incision through the fibrous structure at the pelvis always left a fistulous tract. As was often the case, no stone was found in this instance, but calcareous papillæ were scraped away, and the man had been free from pain since.

THE PRESIDENT remarked that this case was in his ward on the medical side of the hospital a week, and he could say that the relief had been very pronounced since the operation by Dr. Abbe, although no stone was found. He also stated that it was a very gratifying surprise to find how thoroughly the kidney could be inspected, although situated so deeply, after it had once been reached by Koenig's form of incision.

Cases Illustrating Difficulties of Diagnosis in Lesions of the Stomach and Liver.—DR. A. ALEXANDER SMITH related the cases. The first was one of ulcer of the duodenum, the interest of which consisted in the fact that although perforation took place and caused death, yet there was no peritonitis, no tympanites, no obliteration of the liver dulness. One afternoon in the month of January, 1881, he was requested to see a woman who gave the following history: She was about fifty-one years of age, and had been suffering four or five weeks from what she called dyspepsia. She had visited a physician at his office twice, which was all the medical treatment she had received. On inquiry he learned that she had had attacks of vomiting, and that for three or four days she had taken nothing but water. No food could be retained. The earlier history was that she had been in good health until 1879, when, during a stay in Europe, she suffered from dyspepsia, said to be due, by a number of physicians who saw her, to malignant disease of the stomach. She had had two attacks of hemorrhage, her weight decreased from one hundred and thirty-eight to eighty-nine pounds, and the physicians said that she would die. Her husband, however, being a Scotchman, said that she should not die, that she should not see any more doctors, fed her on lime water and milk, and she recovered sufficient strength within three months to return home. Since then she had had ups and downs until about four weeks before Dr. Smith saw her, in January, 1891.

He came to the conclusion that whatever may have been her trouble, careful lavage might give her relief. At 9 P.M. he very carefully washed out her stomach with a mild alkaline solution, and suggested that she take nothing but kumyss. Two hours afterward she said that she felt better than she had felt in three months; took more kumyss. At 2 o'clock awoke again, said she was perfectly delighted, and expressed the belief that the benefit was due to the kumyss, of which she took a little more. Altogether she took the kumyss four times. Early next morning she awoke in great agony, complaining of severe pain about four inches to the right of the mesial line and just below the ribs. She sent for aid in the neighborhood, and when Dr. Smith arrived, about an hour later, she was in apparent collapse. The pulse was fast; the temperature subnormal. There was no tympanites, no obliteration of liver dulness, no general pain, no vomiting. Some relief was afforded by morphine. Dr. Smith thought there was perforation, probably of the stomach, although there was no tympanites. The patient seemed to improve up to midday, then had another attack of pain and collapse, and died about 9 P.M., retaining a clear mind until half an hour before death. At 7 P.M. the temperature rose for the first time, reaching 107.5° F.

Autopsy.—Dr. Biggs made the autopsy, which revealed a little fluid in the stomach, some cicatrization at the pyloric orifice, which was contracted, admitting only a small lead-pencil; there had apparently been no relighting of the process which had existed in 1879. In the duodenum, just beyond the pyloric opening of the stomach, was an ulcer. Between this and the lower surface of the stomach there had been thickening of the peritoneum with adhesion. Evidently the adhesions had before been a protection against perforation of the thin duodenal walls at the point of the ulcer, but finally had become in some degree ruptured, led to a small perforation, and death. The small size of the opening had prevented sufficient escape of gas to be appreciated by palpation. In the pelvic region there was slight peritonitis, which apparently had begun about two hours before death.

Gall-stones and Abscess, with Probable Carcinoma of the Liver.—The second case related by Dr. Smith was that of a man, aged sixty-five, who entered Bellevue Hospital in January, 1892, stating, as he had learned later, that he had cancer of the liver and wished to be cared for. He absolutely declined to give any history of himself, to tell who were his friends or where was his home. He was pale, and had lost flesh. He was examined by several of the physicians, who found what apparently was a carcinomatous tumor of the liver. It was irregular, firm, non-elastic to the feel. There was no temperature elevation. The record after ten days was that there had been no vomiting, no jaundice, no fluid in the peritoneal cavity. On the tenth day, however, there suddenly appeared decided increase in size in the epigastric region, with fluctuation. This was cut into, pus of chocolate color (twenty ounces altogether) escaped, and fifteen gall-stones were removed. The following day eleven more gall-stones came away, varying in size from that of a pea to that of a hazel-nut. The case then appeared to be one of mistaken diagnosis; that it was one of abscess of the liver, or possibly of the gall-bladder, instead of cancer. Still the irregular outline and enlargement of the liver which had suggested carcinoma remained. The man went on to emaciate and died, and they fully expected to have an autopsy, but were disappointed, inasmuch as two priests came and identified him as their brother.

Dr. Smith was still inclined to think the case was one of malignant disease, and that the pus formation was connected therewith; that it was not a kind of pus which would form in the gall bladder. On this point he made the following remarks and cited several recorded cases:

The fact that evidences of the cancerous growth in the liver remained after the evacuation of the pus suggests some doubt as to the locality of the abscess. The pus contained liver-cells in abundance and was of the dark chocolate color so often found in liver abscess. No cancer-cells were found in the pus. It was thought possibly a cancerous mass in the liver might have undergone suppuration. Osler, in his work on Practice,[1] says suppuration sometimes follows secondary cancer. No evidence was found of cancer elsewhere, unless possibly there was cancer primarily of the gall-duct. And this would not seem unlikely, as there might have been a primary cancer of gall-duct, with abscess in the gall-bladder. This view, too, would be strengthened by the fact of the escape of thirty-one gall-stones through the abscess opening.

Case of Medullary Carcinoma, partly Suppurating; Jaundice from Closure of the Common Duct by Cancerous Nodule.—Male, aged sixty five, jaundiced a few days; cachectic appearance; good health till some weeks prior to death; epigastric pains, lancinating tenderness; pulse 70; copious sweat; no liver enlargement, but abdomen very tense, which interfered with palpation; constipation; after two weeks, epigastric fulness and tenderness; ten days later, vomiting, constant pain felt nearer navel; small tumor midway between navel and epigastrium; four days later tumor more distinct and had extended toward navel; fixed; a week later tumor perceptibly increased day by day, was irregular and raised above surface of abdomen, which is flat; epigastric fulness; exhaustion intense; death.

Autopsy.—Lower edge of liver three inches below ribs; liver large and "myristicated" over surface, and embedded in it were several round bodies of grayish-yellow color having the consistence of wax; near extremity of left lobe one of these is softened and broken down as if suppurating, and some of the larger appear in state of incipient softening; head of pancreas cancerous—soft like that of liver; aorta and inferior cava and their branches surrounded by cancerous mass; no ascites; masses chiefly on convexity of right lobe; diseased lymphatic glands formed chief bulk of tumor; felt during life; common duct occluded.[2]

Case of Softening of Cancer.—Female, aged fifty-five; weight of liver, six pounds eight ounces; small tumors varying from size of hen's egg to orange; some solid with softened centres, others contained cavities with yellow serum; tumors consisted histologically of nucleated cells in fibrous alveoli; no cancer elsewhere; gall-bladder small, bound to liver, and filled with stones, and walls were thickened with cancerous tissue.[3]

Specimen in Museum of College of Physicians and Surgeons, New York, from St. Luke's Collection: One-half of Tumor of Liver.—Cancerous cyst would hold a baseball; contained large quantity of pus-like material; cyst-wall irregular and shaggy, and surrounded by cancerous tissue externally; solitary. (The other half of tumor sent to Smithsonian Institute.)

Cancer and Gall-stones.—During twenty-one years (1854–74) not a single case recorded, in post mortem reports at Guy's, in which death occurred, with chronic exhaustion and wasting, as the simple result of the jaundice due to impaction of a gall-stone in common duct.[5] The way in which death is most frequently brought about in persons who have gall-stones is by the development of cancer about the bladder or cancer ducts.[6]

During the same twenty-one years above mentioned, twelve cases such as these.[7] Cancer of bile-passages is associated in many cases with gall-stones.[8] Seven-eighths of all are associated with stones.[9]

Berlin records (1870–89) of 258 cases of hepatic cancer show 25 primary of gall-bladder, 2 primary of bile-ducts, 6 of true primary cancer of liver, 2 of these latter doubtful.[10]

Cancer of gall-bladder is commonly primary, extending to peritoneum and liver secondarily. It is remarkable that in most of these cases the bladder contains stones and the cancer appears to be a sequel thereof.[11] Of 11 cases of cancer of bladder reported by Frerichs, gall-stones in 9.[12] Cancer of gall-bladder is a common sequel of stones. At Guy's Hospital, indeed, it has been found that when death occurs in persons with gall-stones, it is most frequently brought about by cancer about the bladder and bile-ducts.[13] Gall-stones may form in radicles of hepatic duct in the interior of liver. These concretions may partially obstruct and cause dilatation of ducts, and sometimes cause multiple abscesses. A case is reported by Dr. Tuckwell where a large abscess in right lobe, formed in this way, perforated diaphragm, causing empyema and gangrene of lung.[14]

Case of Carcinomatous Cyst of Liver.—Male, aged fifty; cyst contained light-colored fluid and shreddy particles of broken-down cancerous tissue; masses of similar carcinomatous tissue in other parts of liver, chiefly in left lobe, near surface; no other cysts; cancer of pylorus, soft, encephaloid.[15]

Case of Acute Cancer Simulating Suppuration.—Male,

[13] J. W. Ogle: Transactions of the Pathological Society, London, 1858, ix., p. 237.

aged twenty-five, long dyspeptic; in March, indigestion, pain, and vomiting, anæmia, constipation; in April, pain and vomiting increased, chiefly at evening time; in May, tetanoid cramps, pain greatest in flank, vomiting marked, constipation obstinate; rigors, profuse sweats, temperature 102° F. to 103° F.; abdomen very swollen and tympanitic; hepatic dulness increased, covering whole right loin; liver dulness two inches below ribs in mammary line; no jaundice, but bile pigment in urine; after two and one-half weeks of rigors and sweats, making it impossible to distinguish from suppuration, died on May 21st.

Autopsy.—No pus; hard-based ulcer at pylorus; glands at head of pancreas and root of mesentery soft; cancerous growth with effused blood; a reticular carcinoma; liver twice normal size; one-half of substance of liver appeared soaked in extravasated blood.[1]

Thickened Gall-bladder Resembling Carcinoma of the Liver.—Dr. Robert Abbe could recall two cases of gall-stone closely resembling carcinoma of the liver. In one the mass in the region of the gall-bladder was as large as one's fist, perfectly solid to the feel. He thought it was a carcinomatous mass, and therefore hesitated to cut into it. An incision, however, showed that inside the thick walls, a depth of an inch and a half, there was a drachm and a half of pus. A fistulous opening was left; a bad prognosis was made. At the end of six months a gall-stone was seen encrusted in the opening. It was crushed and removed, and six months later when he saw the woman the indurated mass had entirely disappeared.

The association of pus with carcinoma of the liver was not, he thought, rare. He could recall just then one case of empyema of the gall-bladder supposed to be due to gall-stone. The pus was evacuated; no stone was felt; later it was found to be a case of carcinoma at the lower end of the gall-duct with numerous secondary nodules throughout the liver.

Dr. Francis Delafield said, bearing on the difficulty of telling whether there was enlarged liver or something else, that he had seen a case last week in a town outside of New York which had been diagnosticated as waxy liver. The man had apparently a very large liver, extending downward, and the attending physician said that the aspirator needle had been introduced more than once for purposes of diagnosis, but nothing had been found. It seemed evident to Dr. Delafield that the patient was suffering from an abscess somewhere, but owing to the general condition and his own feeling of politeness aspiration was not repeated. The patient died, and it was found that he had an enormously enlarged gall-bladder, which, instead of being enlarged in the ordinary way, was enlarged along the lower border of the liver, symmetrically with that organ.

Anomaly of the Liver Mistaken for Pyonephrosis.—The President mentioned a case in which a tumor was felt and the diagnosis made of pyonephrosis of the right kidney. An able surgeon made an incision in the loin, the mass was felt, and attempts were made to lift it out. Considerable difficulty being encountered, a piece of it was cut off and examined; it proved to be liver. It seemed to have been a case of congenital malformation of the liver in which the organ was much elongated, the left lobe being absent.

Cancer of the Stomach without Gastric Symptoms.—Dr. F. P. Kinnicutt had seen within the last two years two cases of cancer of the stomach, the diagnosis being confirmed by autopsy, in which there were absolutely no gastric symptoms if one excluded failing nutrition and anorexia. In both there was absence of hydrochloric acid from the stomach contents, but it was thought this might be due to a catarrhal condition or atrophy of the gastric tubules; they did not suspect carcinoma.

Gastroenterostomy for Stenosis.—In the absence of Dr. W. T. Bull, a patient sent by him was shown by Dr. Kinnicutt. The man had entered Dr. Kinnicutt's ward at St. Luke's, in 1888, with stenosis of the pyloric end of the stomach and great dilatation. His weight had been reduced to one hundred and twenty-one pounds. At present it was one hundred and eighty pounds. Dr. Bull first performed digital dilatation of the stricture, which gave relief for about a year. He then resorted to gastroenterostomy, it being over two years ago that this operation was performed. The man had since had no trouble with digestion, his bowels were regular, he was in every way well. So far as could be determined, the stomach was not now in a state of dilatation. In this case Dr. Bull made the artificial opening into the stomach for the performance of gastroenterostomy at a greater distance from the pylorus than usual, so that less food would collect and remain in the most dependent part. He asked Dr. McBurney if he did not think that a wise course.

Dr. McBurney replied that he thought it was.

The Dose of Nitro-Glycerine.—The President made some remarks upon this subject. It had occurred to him on a number of occasions, when giving nitro-glycerine for very high arterial tension, that a negative result might be changed into a favorable one by increasing the dose beyond that ordinarily recommended, or until the desired effect was produced. It seemed to him important in giving this agent, as in giving others, that the dose, if the patient could be observed carefully, should be carried up to the point of producing the specific effect, unless some contra-indication should arise. The dose of nitro-glycerine, as stated in the books, was $\frac{1}{100}$ of a grain. But he had recently had two cases in which that amount had been largely exceeded. One of the patients was a blacksmith, sixty years of age, who had marked diffuse nephritis, mitral insufficiency, and general thickening of all the superficial arteries. The renal history and the cardiac history extended over four or five years. The urine was always abundant, always contained granular casts and albumin, and the pulse was always of high tension until he was put upon nitro-glycerine. On January 12th he was given the ordinary dose of $\frac{1}{100}$ of a grain of nitro-glycerine every four hours. It was rapidly increased until, in February, he was receiving a grain every two hours, or twelve grains in the twenty-four hours. By February 21st he received two grains every two hours. It was only under two grains every two hours, day and night, that dyspnœa disappeared, the strength increased, and he was able to go out of his ward. He improved so much that he insisted on going to his daughter's, in Buffalo, and in order to enable him to undertake that journey without receiving such large doses of nitro-glycerine when not under observation, the dose was gradually diminished. He left in March, while taking two grains every four hours. There had been absolutely no unpleasant symptoms attending the use of the drug, but very decidedly beneficial effects. He afterward learned that at Rochester the man became so ill that he was taken to a hospital, where he was recognized by one under whose care, as house-physician, he had been in New York. This gentleman spoke of the large doses of nitro-glycerine which he had been receiving in New York, but the hospital physicians were so horrified that they allowed him to renew them only on his own responsibility. The second day sufficient amount of the drug was obtained and improvement followed at once upon its use.

The second case was one of Bright's disease under his care in the New York Hospital, with pulse of very high tension, occasional attacks of profuse and painful vomiting. The patient said that for two years he had suffered from vomiting before rising from bed in the morning; was then able to get up, but could not work. There was hypertrophy of the left ventricle. About November 1st he began giving $\frac{1}{100}$ of a grain of nitro-glycerine, gradually increased the dose, until he was receiving by the end of the month $\frac{1}{8}$ of a grain every hour. On January 1st he received half a grain every three hours, then half a grain every two hours, then a grain every three hours,

[1] Moxon: Medical Times and Gazette, 1873.

day and night, for several weeks. The pulse improved in tension very much, but occasionally it would return to its original tension and then he would have attacks of persistent vomiting, lasting perhaps three days, and controlled only by enormous doses of morphine administered hypodermatically. During the vomiting attacks the nitro-glycerine was administered in the same doses subcutaneously.

It was of interest to note that when he went off duty Dr. Partridge did not continue the nitro-glycerine, but gave chloral hydrate, fifteen grains every three hours, since which time there had been a better pulse and only one attack of vomiting.

It was a curious fact that some people could not take even $\frac{1}{100}$ of a grain of nitro-glycerine without unpleasant effects.

Dr. Kinnicutt had a case of general arterial sclerosis in St. Luke's Hospital, the pulse being of extremely high tension, the symptoms very distressing. The dose of nitro glycerine in this case had to be carried up to three grains and a half every hour during the waking hours before relief was obtained. These large doses had not only improved the pulse, but had given relief in many ways. He had seen the cerebral condition in general arterial sclerosis very markedly improved under frequent and large doses of nitro-glycerine.

A very striking case was that of a lady who, from being constantly in a dull cerebral state, became, before her death, as lively and happy as possible. She died finally from the effect of the sclerosis, but her life was made much more agreeable to herself and those about her during the last months by pretty continuous dilatation of the cerebral vessels, secured by nitro-glycerine in large and repeated doses. He thought so good a drug should not be abandoned because what generally had been regarded as a proper dose failed to produce the desired effect. The amount should be increased until the physiological effect became manifest. In acute conditions the dose should be frequently repeated, for the effect was very evanescent. In acute œdema of the lungs he had, he felt sure, saved life by giving it every fifteen minutes in doses sufficient to produce the physiological effect.

Dr. Andrew H. Smith asked the President whether the physiological effect of the drug ceased to be produced by a given dose after it had been repeated a number of times.

The President replied that in his experience, when the amount was reached which produced the desired result, it did not become necessary afterward to pass that amount.

Dr. Andrew H. Smith said that his experience had been similar. He spoke of nitrite of sodium as possessing the advantage of producing more durable results.

Dr. Beverley Robinson said the opinion seemed to be general that there should be a high arterial tension before nitro-glycerine was indicated. This was a mistake. He had a case under his care then, in which there was a weak pulse, but not one of high tension. A cardiac stimulant was indicated, but digitalis and other drugs failed to produce the desired result, which was at last brought about by nitro-glycerine.

Dr. Kinnicutt fully concurred in this view.

The Surgeon-General of Illinois.—We hear and read much in these degenerate days of the improvement and purification of the Public Service, but it has been reserved for the present Governor of Illinois to show the estimate placed upon professional ability and experience by a thoroughgoing politician. The telegraph informs us that a young graduate of the Hahnemann Class of '87 has been appointed Surgeon-General by his Excellency Governor Fifer, to fill the vacancy caused by the death of General Matthews. The action of the Governor in selecting this inexperienced young person for so important a position is inexplicable on ordinary grounds.

Correspondence.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE ANNUAL PHYSICIANS' DAY—THE SPECIALIST QUESTION—THE DISPENSARY ABUSE AND ITS REMEDY—THE CONDITION OF THE GERMAN PHYSICIAN—A WARNING TO INTENDING MEDICAL STUDENTS—THE ADMISSION OF WOMEN TO THE UNIVERSITIES—INCOMES OF BERLIN PHYSICIANS—THE ECLAMPSIA BACILLUS—THE CHOLERA—THE COMING MEETING OF THE SOCIETY OF PHYSICIANS.

Berlin, July 11, 1892.

Besides the scientific congresses which convene yearly, we have an Annual German Physicians' Meeting, in which medical questions and ethics of the profession are discussed.

This congress took place this year at Leipsic, and, among other important topics, the specialist question was thoroughly discussed in a paper by Dr. Stimmel, of Leipsic. Among other things, the speaker held that specialism had developed certain phases which were disadvantageous not only to the ordinary practitioner, but to the public at large.

That specialists are necessary nobody would deny, and if they did not exist it would be necessary to create them. The polyclinics or dispensaries are an injury to the profession, and are of no advantage to the public since the creation of the Sick Fund.

The Medical Society of Leipsic resolved some time ago that only instructors in the different branches of medicine should be allowed dispensary duty, and this for the purpose of securing material for instruction only.

Since that time dispensaries in Leipsic seemed to have vanished. There are many physicians calling themselves specialists, as a sort of decoration, who try by the aid of a dispensary to enlarge their general practice.

An examination of specialists, which is really a desideratum, would do much to elevate the standing of the physician. Upon the results of such examinations the applicants could be divided into specialists of the first and second class. The institution of such a state examination would modify the number of specialists, and would tend to establish specialism upon a firm foundation.

The number of general practitioners would be thereby reduced, as the majority of young physicians would then strive to pass one or two examinations for the rank of specialist of the first or second class.

Dr. Becker, of Berlin, thought it would be manifestly unfair to forbid the young specialist, who had no reputation, from taking general cases.

Dr. Martin, of Berlin, proposed that a business committee of the Medical Society be instructed to publish yearly, about the time of the preliminary examinations in medicine, the true facts pertaining to the medical profession at that time, and to warn those who seek a livelihood from the practice of medicine to abstain from studying it.

The reasons for this, the speaker continued, were to be found in the laws authorizing the existence of medical insurance, whereby hundreds of thousands of patients go to a few privileged physicians. Six years ago the United Medical Societies warned the public concerning the difficulty of making a living from the practice of medicine, but this warning had evidently been without effect, for in the winter session of 1886–87 there were 7,788 medical students, and in the winter of 1891–92 there were 8,902. There has been, therefore, a decided increase.

In 1886–87, 998 candidates passed their examination and were admitted to practise. In the examination of 1891–92, 1,571 new physicians were graduated.

In the winter session of 1885–86, 442 physicians died. In the winter session of 1891–92, 452 physicians died. Added to this are 59 physicians who have either emigrated or have retired from practice.

In the year 1885, Germany had 46,500,000 inhabitants. In the year 1890 the population was 49 000,000. The former were attended by 16,692 physicians, the latter by 19,630.

In the year 1885, the ratio of practitioners to the population was $3\frac{3}{4}$ to 10,000; now it is 4 to 10,000. The population of Germany has increased since 1886–87, $9\frac{1}{10}$ per cent. In the same period the number of physicians has increased $15\frac{4}{10}$ per cent.

Six years ago, when this warning was sent out, there were 4,000,000 members of the Sick Insurance. To-day there are more than 6,000,000, and the membership is constantly increasing.

Besides these disagreeable facts there was, the speaker held, still another danger, viz., the agitation to permit women to study medicine. The Prussian Universities, which were questioned on this point for an opinion, replied in favor of admitting women. The only requisite is that they must possess a certain amount of preliminary education. If this last point is the only hindrance, we can naturally expect to see a great many women studying medicine.

In Berlin there are 1,615 physicians and 132 dentists, a total of 1,747. Of these there are 855 who do not have an income of 3,000 marks, or $750 per annum. There are 892 who do not depend on their practice for a livelihood; 150 have much less than 3,000 marks; 250 physicians have an income over 8,000 marks, and 170 over 10,000 marks. The number of physicians who get rich is very small indeed, while the number in debt is extremely large.

These disagreeable circumstances exist chiefly in Berlin, and the condition of physicians in the provinces is somewhat better, but not much.

The following resolution was adopted by the Society: "We desire to express the fact that the severe conditions of medical life do not warrant the increase of physicians in greater proportion to the increase in population."

A very interesting, and probably practical, discovery is that of the eclampsia bacillus by Dr. Gerdes, of Halle. Some time ago Gerdes called attention to the existence of a bacillus which he thought played an important part in the etiology of this disease. He now states that he has demonstrated the existence of colonies of this bacillus in the body of a patient who died from eclampsia.

The bacilli were found in the lungs, in the septum ventriculorum, in the placental areas, in enormous quantities, and in the liver and kidneys in smaller numbers. They did not exist in the spleen.

Gerdes was able to obtain pure cultures of the bacillus. This proves, he held, that eclampsia is an infectious disease. Numerous interesting questions have yet to be discussed in this direction, but Gerdes believes that the bacilli enter through the cells of the decidua as a result of endometritis, and are forced by the uterine contractions into the sinuses, and thence into the general circulation. The following were the conclusions of his paper: 1. The eclampsia bacillus is the only cause of eclampsia and is found in no other disease. Infection occurs through the uterus, most probably in consequence of an existing endometritis. 2. The causes of other forms of convulsions during labor are decidedly different, post mortem, from those giving rise to true eclampsia. 3. Eclampsia is an anatomically limited and characteristic disease. 4. The existence of the well-marked lesions found in eclampsia is not sufficiently explained by the mere presence of the specific bacillus. Most likely the direct or indirect causes are the toxin of the eclampsia bacillus.

The spreading of cholera from Russia to Prussian soil is feared, especially so since cases are reported from Paris. The German Government is carefully watching the progress of the disease in Southern Russia, and has established in Königsberg a sanitary commission to prevent any further advance of the disease.

We do not expect that cholera will force its way this year into Germany; but, owing to the good soil which the disease finds in Russia, it is still not improbable that it may spread. Luckily the mortality of the present epidemic is a relatively small one.

The programme of the Sixty-fifth Meeting of the Society of German Naturalists and Physicians, to be held in Nürnberg, September 11th to 17th, has been published. The meeting promises to be a very interesting one. Among those who are announced as readers of papers are His, Pfeffer, Hensen, Ziegler, Strumpell, Günther, Huppe, and others.

THE HEALTH RESORTS OF THE RIVIERA.

(Continued from page 203.)

IX.—San Remo.

(From our Special Commissioner.)

GARBAGE REMOVAL — THE DRAINAGE QUESTION — LEPROSY IN THE GENERAL WARDS OF THE OSPEDALE CIVICO —A TRIP TO ARGALLO, THE MOUNTAIN SOURCE OF THE DRINKING-WATER—THE NEW AQUEDUCT—FAULTY METHOD OF DOMESTIC WATER DISTRIBUTION—THE STABILIMENTO DEI BAGNI—THE PROJECTED CASINO OR KURSAAL—MEDICAL OPINIONS OF SAN REMO—OUT DOOR LIFE AND AMUSEMENTS—COST OF LIVING.

The slovenly method, still in vogue at most of the Riviera resorts, of dumping all kitchen refuse, ashes, leavings, etc., into the street is strictly prohibited at San Remo. Such matters are now put into receptacles and carted away at the expense of the city, the carts making two daily rounds, one early in the morning, and one in the evening. The arrival of the garbage-cart is announced by the blowing of a horn. It appeared to me that the removal carts really performed the purpose of their existence, a truly novel sight to New York eyes, where the original function of collecting has been so successfully perverted into one of bounteous distribution of their pleasing contents. But as Carlyle's schoolmate, Sandy Macpherson has said: "Mony things please the folk in Lun'on that wouldna gang doon in Glasgow."

At the present time San Remo possesses in some of the streets of the old town, as well as in the main thoroughfares of the newer quarters, a system of large-calibre, old-fashioned drains. These are intended to convey surface water only, and they all empty into the sea, either directly upon the shore or at a little distance beyond it. This is, of course, decidedly objectionable.

In the streets numerous gratings are seen, which are placed horizontally and take the place of culverts. As a matter of course much solid matter finds its way into these drains, and as flushing tanks are not employed, the cleansing is left to nature. There is no doubt that the heavy rainfalls of the spring and autumn months effect, periodically, a thorough enough purification of these canals; but for the greater part of the year they must be choked up with decomposing matter that at times poisons the atmosphere.

In this unsatisfactory state of affairs it is fortunate that the surreptitious connection of house soil-pipes with street drains (which is as universal on the Riviera as it is dangerous) has not yet been generally practised at San Remo. But surely some provision should be made for keeping those drains which now exist permanently clean and clear of accumulating rubbish. Drains are supposed to be conduits, and not depositories of filth.

As for the numerous mountain streams coursing through the town, such as the Torrente di Bernardo, della Foce, S. Francia, Lorenzo, S. Martino, but especially the large and central S. Romolo—which runs partly underground through the heart of the city—not one of them is free from the reproach of contamination. Laws against fouling the so-called torrents exist. But it would require more than one educational campaign, including the practical demonstration of self-interest, to wake up an ignorant populace to the necessity of keeping pure

these open water courses. Moreover, in spite of the recent establishment of six or seven public lavatories (*lavatorio publico*), the hereditary instincts of the washerwomen still send them by preference to the dirty streams. There they heroically attempt to clean their clothes in any gathering little pool. The result is that after a mild ducking in cold water, followed by the regulation violent pounding between two stones, the linen is apt to be rather the worse for its alleged wash. Let some philanthropist organize a Society for the Propagation of Modern Methods of Running the Laundry, and a long-suffering community will not begrudge him a monument.

The cesspools of San Remo are of two kinds, the *pozzi neri*, or cemented pits, and the *pozzi morti*, or earth pits. Both are, of course, objectionable in growing towns. In the old quarters, the house soil is merely allowed to collect in bins or barrels, which, when full, are carried to the olive forests for manure.

Plans and proposals for a new drainage system are much talked about just now at San Remo. But I found that considerable differences of opinion exist in regard to the propriety of establishing modern sewerage here.

Dr. Freeman, for one, does not hesitate to attribute the general good health of the place to the absence of sewers, which he regards as prolific carriers of infection. There is this to be said in defence of his position, viz., that unless house connections are properly made, public sewers may indeed become breeders of, rather than safeguards against, contagion.

But no valid objection exists to a system of sewerage that includes the provision of proper house cut offs, with vent-pipes for all traps, such, for example, as is now being established at Cannes.

To judge from the plans now under consideration at San Remo, and which the authorities kindly gave me an opportunity to study, I should say that the tentative way in which sewers are to be laid down at that place will at least afford an opportunity to practically test the efficacy of the new system, without plunging the tax-payers into needless expenditure that would be a hindrance to later extensions or improvements.

It is certainly satisfactory to note that a large main is to be immediately put down in the bed of the most objectionable stream, viz., the San Romolo, which will convey the sewage some hundred yards out to sea to the west of the harbor. Four other main collectors are also in contemplation, each one to take its contents hundreds of yards out to sea. The Rivo Berigo, the Torrente S. Francesco, S. Lazaro, and Rivo Rubino are the streams, taken in their order from west to east, which are to have these canals.

It would, of course, be preferable to construct one main collecting pipe for all these sewers, and empty everything at a safe distance from the town, either far to the east or to the west.

The original cost of construction would thereby be made rather greater. But sooner or later this system will have to be adopted, and it is open to question whether subsequent changes may not entail a heavier expenditure than the immediate adoption of the more radical plan. This, however, is a matter for engineers to decide rather than physicians. But, in any event, San Remo might profit by the mistakes of towns like Nice and avoid a blundering repetition of costly errors. As for the propriety of putting collectors in the beds of streams that run dry during the summer months, that also is a question for the engineers to grapple with.

Through the courtesy of Dr. Peracca, the Medical Director of the General Hospital (*Ospedale Civico-Mauriziano*), I had an opportunity of examining this institution, which is beautifully situated on the eminence just below the sanctuary of the Madonna della Costa. During that trying ordeal of her husband's last illness, the Empress Frederick paid a daily visit to this hospital, and never omitted to look from the Director's window on the picture of restful beauty spreading out before her tear-stained eyes. This spacious hospital appeared to be a clean and well-managed charity. But the feature of special interest to me was the presence in the general wards of four advanced cases of leprosy. Formerly over forty lepers, coming from all parts of Italy, and even from France, were cared for here. But the lepers have all died off or have been removed, and new cases do not now seem to occur. Leprosy is not considered in the slightest degree contagious here, and Dr. Peracca tells me that since 1846, when the close supervision of the leper colony began, nothing has occurred which could be in any way construed as pointing to contagion. When it is remembered what a hue and cry is raised in our country when some poor leper is hunted up (or run down) by the reporters, this demonstration of apparent harmlessness to others of that truly loathsome malady, ought to interest the medical experts of the lay press.

Through the courtesy of Signor Marsaglia, the well-known railroad contractor and one of the builders of the famous St. Gothard tunnel, an interesting excursion to the distant mountain springs of Argallo was undertaken. Sir Spencer Wells, who was spending a few days at San Remo on his way home from India, was one of our party. We were first taken in fine four-in-hand coaching style through Taggia, the birthplace of Ruffini, and other ancient villages in the valley of the Argentina, to the foot of the mountains. Here we were duly transferred to the tender care of orthodox mules and picturesque muleteers. A toilsome and sometimes perilous ascent was then effected, after a fashion most proper and becoming to so distinguished a party. For, in addition to Sir Spencer and the "American Medical Commission of the Congress of the International Association of the United States of the North" (which is the way they had me down for short, although I never intentionally wounded their feelings), all the local celebrities, members of the press, and representative people generally, had been invited to participate. There was a goodly number of us therefore. For it so happens that the type of perfect manhood in this last decade of our calumniated century rarely refuses the occasional free lunch that blossoms along the tortuous path of life.

It is unnecessary to expatiate on the varied beauty of the scenery which met the eye at every turn along our route. Nor will I enlarge on the novelty of many situations in which I unwillingly found myself, while fording mountain torrents, climbing rocky paths so narrow that one false step would have meant a fatal fall down a steep precipice, or zigzagging it up and down wildly romantic declivities, always on muleback, with the muleteer firmly guiding the brute by hanging on to his tail. Once, and once only, I purposely descended (I do not now recall the precise number of unpremeditated descents which I accomplished), and grasping the animal's rudder, a stumpy apology for a tail, I made a bold effort to steer my own long-eared craft. But the cunning beast knew the difference. And a moment later I did too. For when that sapient mule made his little hind-legged bow, I felt an irresistible impulse to describe a graceful segment of a circle through the pellucid atmosphere, and having regained my mental, moral, and corporeal equipoise, I found myself securely settled between two jagged rocks, that I had not until then recognized as part of my programme. After my disinterment I always gave the mule the benefit of every doubt. And from the way our henceforward harmonious efforts were rewarded by "getting there" on time, I am prepared to generalize as to the best method of treatment of an acute attack of mountain donkey. But I shall never be prepared to forgive my fellow-mulebackers the long look of unfeigned cheerfulness with which my extempore performance was received. Such mirth is poison to the pride of spirit and balmless to the lacerated flesh.

If I only knew how, I would willingly describe the character of the cold collation that our hosts had so bountifully provided for us in the little house of the guardian

of the springs, high up in the mountain fastness of Argallo, where, under the huge chestnut-trees, recent snow lay sprinkled in pretty little patches. The resources of Italy in caseous, vinous, carnous, and other edible and potable directions were probably never more forcibly brought home to the experimenting foreigner than on this memorable occasion. Soon everybody had a toast to offer, and everybody else gleefully responded. Sir Spencer remarked in mellifluous Italian, what I plagiarized into abstract French, and a German medico dislocated into what he said was English, and what the native Italian contingent all allowed was so—namely, that we, the grateful survivors, had "had a splendid time," and that the *acqua potabile di San Remo*, while good, was not as good as the various brands of their *vino molto bono*, nor as the huge slabs of conglomerate formation called *salani*, and those picturesque laminæ of an upper pleiocene stratum abounding in garlicky nummulites so innocently termed sausage. The glowing terms in which the local papers chronicled this memorable tour are likely to mark a distinct epoch in contemporaneous Italian journalism. And, if I am not mistaken, Sir Spencer will take England into his confidence through the columns of the London *Graphic*.

But the cream of all this literary milk naturally goes to the readers of the RECORD, as innate modesty compels me to reluctantly admit.

As for the main object of our visit, the inspection of the Argallo sources, a decidedly favorable impression was made upon us. The limpid water as it filters down the mountain sides, is caught up into a closed clay conduit and conveyed underground to a first reservoir, whence iron pipes take it to the city of San Remo. Numerous reservoirs are established along the course of the aqueduct, which is in itself a remarkably clever piece of engineering. The expense of this laborious undertaking, I am informed, was too considerable for the funds in the city treasury. And had not the far-reaching good-will of the wealthy brothers Marsaglia been enlisted in the work, it could not have been carried out. The water is conducted from an altitude of nearly twenty-three hundred feet, through miles of mountains, hills, and valleys, by huge U-shaped siphons, down to the level of the sea. The supply of water is so abundant that the unused overflow is said to be more than sufficient to serve as motive power for a plant to supply all the streets, buildings, and private houses of San Remo with electric light. In fact, a definite proposition to this effect has lately been made, and is now before the authorities.

San Remo having secured an over-abundance of excellent water, it would be supposed that every house was amply supplied therewith. This is, however, not the case. The way the water is penuriously doled out to most houses is quite faulty, though I am informed that the stinginess of landlords is chiefly responsible for so unsatisfactory a state of affairs. But the San Remo water is cheap enough and it ought to be much more freely dispensed than is now the case. Houses and villas at present have the usual leaden pipes connecting with the main, but only the officials of the water company regulate the supply, which, as already stated, is generally inadequate. Moreover, a tank is interposed between the main and the house hydrants, so that the really fresh mountain water is not *de facto* available. Simple and cheap water-meters would obviate the necessity for tanks, and yet permit the company to regulate the supply. Of course, new meters mean bigger bills, but when they are also synonymous with unlimited quantities of fresh water all grumblings ought to be suppressed.

I must here mention a decidedly dangerous arrangement which I have seen in some houses, namely, that of allowing an overflow pipe from the roof tank holding the entire supply of drinking-water to empty into the drains in the streets. A more deliberate bid for disease is not likely to be found anywhere. Fortunately most houses allow the overflow a safer exit.

In the analysis of San Remo drinking-water [1] 5,000 grammes of water contain: Organic substances, a mere trace; chlorine, 0.00065 gramme; sulphuric acid, 0.027 gramme; salts in solution, 0.08 gramme; insoluble salts (chiefly carbonate of lime), 0.35 gramme. Total inorganic matter, 0.43 gramme. The hardness of the water in 70 grammes is 19.5.

A large bathing establishment has recently been completed here, and warm sea-baths may now be taken throughout the winter season. Open-air bathing is not popular except during the heat of summer, when the foreign colony has departed, and a moderate influx of Italians occurs. The beach is a sandy one and has a very gradual incline, but one of the main drains empties near it, and the odoriferous gas factory liberally dispenses its peculiar smells in the neighborhood. On the authority of the Sindaco di Sanremo, I may state that the gas factory will be soon removed beyond the olfactory range of the bathers.

The San Remese are rather proud of their Casino—a magnificent new building; so new, indeed, that it has not yet been erected, save in the fervid wish of those friends of the place who know that judicious expenditure is apt to prove a profitable investment. The Mayor informs me that the building, when completed, will represent something like the "kursaals" of German watering-places, *i.e.*, a rallying-point for the foreign colony, where concerts, fairs, balls, and other entertainments will be provided. As gambling is to be strictly prohibited at this place, the Casino of San Remo will differ, in one important particular at least, from similar establishments elsewhere on the Riviera.

Families are to be attracted rather than repelled. The provision of wholesome entertainment without any taint of "games of chance" will doubtless make the Casino a welcome and popular institution, except among the more frivolous. But as the latter will naturally gravitate toward the green cloth of Monte Carlo, their disapproval will be creditable rather than otherwise. Spacious reading-rooms, salons de conversations, billiards, bowling-alleys are not to be forgotten.

There is a singular unanimity of opinion among medical and other competent writers relative to the advantages of San Remo as a winter health resort. In Dr. Hassall's works many excerpts from various authors will be found. I have made the subjoined selections, as embodying the gist of the information contained in the principal publications. Dr. Hassall himself has given the following fair *résumé* of the characteristics of the climate: "It is moderately warm during the winter, even in the shade, the temperature being fairly equable. It is very sunny; there are but few days on which the sun does not shine, and the duration of the sunshine is very considerable. In consequence of the power of the sun and the duration of the sunshine the air is for the most part clear, the sky bright, and there is abundance of light. There are but few days on which rain falls, and the air is moderately dry. Owing mainly to the sea and land breezes, the air is kept in movement day and night, and is consequently refreshing and exhilarating. The combined effect of these several characteristics is that the climate of San Remo is, during the winter season, moderately stimulant and decidedly tonic. A climate possessing the qualities above mentioned cannot fail to exert a very powerful influence on the functions of the body, for good or evil, in a great variety of diseases. Owing to the mildness of the climate there is less wear and tear and less strain. The several functions are performed in a more moderate and uniform manner. There

[1] The official document submitted to me bears the following superscription:

"CITTÁ DI SANREMO.

"Esame chimico delle acque potabili da condursi nella Cittá di Sanremo, che servi di base al contratto conchiuso col Signor Commendatore Giovanni Marsaglia par la conduttura delle acque d'Argallo, come da appositto documento esistente nell' archivio comunale."

being less expenditure of power and less waste, a smaller quantity of food is required, and the stomach has less work to do. The circulation, in particular the heart and its vessels, is exempt from the severe strains entailed by extremes of cold and heat, and which in themselves are often injurious, and not unattended with danger. The action of the sun on the human body is very complex; the effects are not confined to the warmth derived from its calorific rays; the luminous and chemical rays all exert powerful effects. The sun acts as a stimulant to most of the bodily functions: to elimination, secretion, and absorption; it determines many chemical changes, and promotes sanguification and the coloration or bronzing of the skin."

Dr. C. T. Williams has thus written: "The climate of San Remo is warm and dry, and from the protecting ranges not rising precipitously as at Mentone, but sloping gradually back, the shelter from the northerly winds is not quite so perfect as at the last-named place; at the same time the vast olive groves screen the locality from any cold blasts, and the breezes which filter through the olives impart a pleasing freshness to the atmosphere and remove sensations of lassitude often experienced in well-protected spots. The size of the sheltered area gives patients a considerable choice of residences, which can be found either close to, or at varying distances from, the sea, according to the requirements of the case."

Contrasting San Remo with other Riviera resorts, Dr. Prosser James says: "San Remo, with its warmer and more equable temperature, its calmer atmosphere, its tone-giving elasticity, its dryness and other attractions, must be preferable to any of the other stations in certain cases. These are, for the most part, those for which other localities are too stimulant."

The late Dr. Rose, who lived and practised for some years at San Remo, has thus written: "Its climate is intermediate between the east and west ends of Mentone, not so warm as the former, and more sheltered than the latter, the air being also more soothing than at Cannes, Nice, and Mentone. This depends on the fact that the ground is covered to the water's edge with orange, lemon, and olive trees, thus preventing too rapid evaporation, and the soil, being principally clay, prevents the rain percolating through so rapidly as it would in sandy and gravelly soil."

Finally, Mr. Aspinall has expressed the following views:

"San Remo has a delightful climate, so fresh and bracing and yet so balmy; there is even a certain amount of humidity in the air, especially at the east end of the town, which suits some invalids better than too dry an atmosphere. As far as my own experience goes I have not found any other climate from which I have derived so much benefit, though I have passed a winter in Madeira, another in Egypt, and shorter periods in Rome, Naples, and Sorrento. It combines in a modified degree the invigorating qualities of Nice with the warmth of Mentone, but without its closeness. There must be something peculiarly soothing and conducive to sleep in the air of San Remo."

It would be needless to further multiply opinions, as they are all composed in the same strain.

The walks in and about San Remo offer sufficient attractions to make them enjoyable, although there is not the great extent and variety found at Nice and Cannes. Mountain climbing and donkey rides may be profitably indulged in by the more robust. It is quite unfortunate that the railroad has been allowed to run close to the shore, as the town has thus been robbed of a sea promenade that might have rivalled the famous Promenade des Anglais at Nice. Excursions in carriages are less popular here than at other places, for the roads are dusty and offer few compensatory inducements in the way of beautiful views.

There is music three times a week in the Giardino Publico, and genuine Italian opera is done at the theatre. Garden parties, dances, teas, picnics, tennis, boating, sailing, and allowing ideas to sprout by "just sitting still" in the vivid fructifying sunshine, are all included in the category of fun and frolic at this place. I must not forget to mention that San Remo also boasts of several clubs, one of which is English. At the principal Italian club, the *Circolo Internazionale*, where several balls are given, foreigners on proper introduction are readily admitted.

The Carnival, the tail-end of which only I underwent, is not over-vigorous at San Remo, so that those who hanker after a really robust variety of that peculiar sport are referred back to Nice.

On the whole, however, the reproach sometimes levelled at San Remo of being hopelessly dull and tame is founded only in a taste for pleasures that a self-respecting health resort has no business to provide.

It has been repeatedly stated that living expenses were much lower in Italy than in France. That may be so. But the Riviera has its own particular tariff, whether you live east or west, in Liguria or in Provence. Housekeeping is, however, actually rather less expensive at San Remo than along the French Riviera. But this advantage is offset by a lower food standard, and by numerous petty vexations in regard to servants, which form a standing grievance here, although they undoubtedly promote fluency of conversation at social gatherings, where the ladies numerically predominate to a rather alarming extent.

First-class hotels, like the West End and the Hotel des Anglais, charge first-class prices, and I doubt very much whether Americans would be satisfied to remain long at any of the cheaper houses. If you have money to spend, life will be made comfortable enough for you here. But if you go there for the sake of economy, you will wish you hadn't before the end of the season.

THE BRITISH MEDICAL ASSOCIATION.

(From our Special Correspondent.)

NOTTINGHAM, July 29, 1892.

THE Sixtieth Annual Meeting of the British Medical Association closed its sessions here to-day. The Association is now getting to such a respectable age that it is the exception—rather than the rule—for an annual meeting to be held in a town not previously visited. One reason for visiting towns a second time is no doubt to be found in the fact that the increasing numbers of those who attend the annual meetings render it necessary to select a town for the annual meeting where there is ample accommodation for the members and suitable rooms wherein to hold the meetings. This is the second time the Association has met in Nottingham.

The First General Meeting took place Tuesday morning, July 26th, at half-past eleven. The chair was taken at first by the President, Dr. J. Roberts Thomson, of Bournemouth, who signed the minutes of the preceding Annual Meeting and then vacated the chair in favor of the President-elect, Mr. Joseph White, of Nottingham. The usual vote of thanks to the retiring President was carried, and he was elected a Vice-President for life. The report of the Council was then presented and adopted. In seconding the motion to adopt the report, Sir William Moore spoke with favor of the proposal to admit women doctors into the Association, and his remarks on this head were well received by the audience. Dr. Rentoul asked for more information as to how the amount (five thousand pounds) put down for editorial expenses was expended. Dr. Drage complained of the Council speaking in the name of the Association without consultation with the branches. The adoption of the report of the Parliamentary Bills Committee was then moved by Mr. Ernest Hart, who drew special attention to the grievances of the Irish dispensary medical officers. Dr. Walter Smith, of Dublin, contended that the English district medical

officers had as much of a grievance as the Irish. The report was adopted. Dr. Norman Kerr moved the adoption of the report of the Inebriates Legislation Committee. Dr. Usher, of Melbourne, seconded the motion, which was agreed to. Surgeon-Major Pringle drew attention to the evils of intoxication from other causes than alcohol, as from opium or chloral, and the necessity of dealing with them. Surgeon-General Cornish presented the report of the Committee on Scientific Investigation into the Condition of School Children and moved its adoption. The Committee had, in conjunction with a committee of the Charity Organization Society, conducted an investigation into the physical and mental condition of 50,000 children. The correlation of visible signs with low nutrition and mental dulness had in many cases been demonstrated. The report of the committee appointed to investigate hypnotism was then presented. The committee reported that they had satisfied themselves as to the genuineness of the hypnotic state, but that no phenomena which had come under their observation supported the theory of animal magnetism. They thought hypnotism could relieve pain. After some adverse criticism on the report, an amendment was finally carried referring it back again to the committee.

The second session was held at half-past eight in the evening. After introducing to the meeting a number of foreign members, delegates, and guests, Mr. White delivered his Presidential Address. (See p. 168.)

A vote of thanks to the President for his address was moved by Professor Hingston, of Montreal, seconded by Sir Frederick Bateman, and briefly acknowledged by the President.

The report on Railway Servants' Eyesight was then presented by Dr. Mackey, of Brighton, and that on Anæsthetics by Mr. Victor Horsley, F.R.S. Surgeon-Lieutenant-Colonel Ince then moved a resolution deprecating the payment of the travelling expenses of the members of the Council. After some discussion this was lost, and the meeting terminated shortly before eleven o'clock.

The various Sections commenced work Wednesday morning.

In the afternoon the Second General Meeting took place. The first proceeding was the reading by the General Secretary of the list of members elected by the branches to serve on the Council for the ensuing twelve months. The President then announced that the Council had received an invitation from Newcastle-on-Tyne to hold the next annual meeting in that town. It was resolved that the invitation be accepted, and on the motion of Dr. Withers Moore, seconded by Mr. Wheelhouse, Professor Philipson was elected as the successor to Mr. Joseph White in the presidential chair.

Professor Cuming, of Belfast, then delivered the Address in Medicine, selecting as his subject "The Position of Medicine in the General World of Thought and in Relation to other Sciences." (See page 169.)

The Third General Meeting took place on Thursday afternoon. The first item on the programme was a proposal to alter a by-law of the Association made fourteen years ago, whereby women were to be excluded from joining the Association. This was brought forward by Dr. Galton, seconded by Mrs. Garrett Anderson (the only lady member at present), and supported by Mr. George Brown, Surgeon-Major Pringle, Surgeon-General Cornish, and others. It was finally carried by a large majority, but the alteration has to be confirmed by a Special General Meeting to be held next month before it will become binding.

The Address in Surgery was then delivered by Professor Hingston, of Montreal, Canada. (See page 168).

The usual vote of thanks was proposed by Mr. Lawson Tait, seconded by Mr. Croft, and carried amid applause.

The Fourth, and concluding, General Meeting was held on Friday afternoon. At this session the Address in Bacteriology was delivered by Dr. G. Sims Woodhead. (See page 170.)

The usual vote of thanks was passed to Dr. Woodhead for his address, on the motion of Surgeon-Colonel Harvey. A resolution affirming the necessity of continuing and extending experiments on living animals was then moved by Mr. Jonathan Hutchinson, seconded by Dr. Ransom, and carried unanimously. Certain resolutions on the subjects of cremation, hypnotism, and the examination of school children, which had been passed last year in the meetings of Sections, were also confirmed. Votes of thanks brought the proceedings to a close.

I must add a few lines about the Annual Museum As usual this was very extensive and filled a considerable amount of space. In the pathological department Dr. Colcott Fox and Dr. Radcliffe Crocker exhibited a number of interesting colored drawings of various cutaneous affections, and Dr. Byrom Bramwell sent a number of graphic illustrations of disease. A number of specimens from the West Riding Lunatic Asylum were on view. I noticed particularly a specimen showing erosion of the vertebræ by an aneurism, to which a memorandum was attached stating that the patient was a gymnast up to the time of his death.

A small Sanitary Exhibition was also on view, which was unconnected with the British Medical Association. This consisted almost entirely of exhibits illustrating drainage and sewerage. I noticed two exhibits demonstrating how lead pipes can be used with safety for water supply. One of these was not novel, block-tin being used to line the lead pipe, but the other was rather ingenious, a collodion compound being applied to the interior of the pipe as a protective.

PLAN FOR A SELF-SUPPORTING SOCIETY FOR THE SUPPRESSION OF THE ABUSE OF MEDICAL CHARITY.

To the Editor of the Medical Record.

Sir: I would suggest the following as a scheme for the organization of a society to repress the dispensary evil. The society shall have at each dispensary a clerk whose duty it shall be to fill out certain blanks and obtain the signatures to them of applicants for medical charity, and who shall have duties covering a certain district of the city.

Blank No. 1.

Name ....., Address ....., Age ...., Occupation ....., Income when employed ...., When last employed ...., Number in family...., Value of property owned by applicant or responsible relative ...., What is the largest amount that you or your family can pay for the treatment you desire, $ .... per week, $ .... per visit? Could you pay in the future ....?

To whom can you refer to verify the above statement:

Name ..... Address where he can be found at ..... o'clock.

I hereby declare the above true to the best of my knowledge and belief.

Signature of applicant for medical charity:

....

I know the person named above and believe the above statements to be true.

Signature of person named as reference:

Name ....., Address .....

Blank No. 2.

In consideration of medical treatment received at an institution under the supervision of the Society for the Prevention of the Abuse of Medical Charity, I agree to pay to said society $.... on demand of an agent of said society.

Signature of patient .....

The amount to be inserted is to be equal to what a physician treating the case in his office would charge a similar patient for a similar service.

The above note is only to be enforced in case of fraud.

The city would be divided into districts, each under the care of one of the dispensary clerks, whose duty it would be to verify the addresses of applicants from his district, to obtain the signatures of references, and to report to an investigation department of the society such cases as seemed to require investigation, said clerk to receive a percentage of money recovered from cases reported by him for investigation.

The work of the dispensary clerks would thus be chiefly routine, and they would not command high salaries.

The investigation department would be under the control of men of known good judgment, or this work might be entrusted to the Charity Organization Society. When fraud was detected the notes in the hands of the society would be collected by the usual legal methods and the proceeds used for the support of the society.

If there were a surplus it might be used to buy whiskey for the men and fine clothes for the women who might be deprived of these luxuries when compelled to pay their doctors. Or a "law dispensary" might be started where all comers would receive free legal advice, thus giving another learned profession the benefit of a dispensary system.

The working of the society would be as follows: The clerks would fill out Blank No. 1 for each new applicant, and see that each patient signed Blank No. 2, and that the physician inserted the value of the services rendered. At the close of dispensary hours all these papers would be sent to the society's office, where Blanks No. 2 would be filed and Blanks No. 1 sent to their respective districts for the preliminary work by the dispensary clerks. Anyone giving false information or able to pay doctor's fees would be reported to all the dispensary clerks, and in case he should apply a second time the clerk of the dispensary to which he applied would report him to the proper dispensary authority as not a fit subject for medical charity. Cases desired for clinical purposes could be given passes admitting them to free treatment.

Louis F. Bishop, A.M., M.D.

24 East Forty-first Street.

WOMAN'S BRAIN.

To the Editor of the Medical Record.

Sir: There is a fallacy in Sir J. Crichton Browne's comparisons of the weights of the male and female brains which ought not, I think, to pass unnoticed in an article of its pretensions to scientific accuracy. He compares the height of men and women with the weight—that is, the mass—of their brains. But it is one of the first principles of mathematics that the mass or bulk of similar bodies varies as the cubes of their corresponding dimensions. If, for instance, we suppose a man four feet, and another eight feet in height, similarly proportioned in all respects, every organ of the latter, including the brain, should weigh, not twice, but eight times as much as of the former.

He gives the average heights of the sexes, as shown by his measurements, as 1.702 metre for men, and 1.575 metre for women. The respective cubes of these dimensions are 4.913 and 3 852, a difference of 27.7 per cent. of the latter number in favor of the male. This is not, I think, very far from the actual difference in body-weight of the sexes, allowing for the state of nutrition. But the difference in brain-weights is only 127.68 grammes, or 10.44 per cent. of the average weight of the female brain. The comparison, so far as it has any value, is decidedly in favor of the latter.

W. L. Worcester, M.D.

Little Rock, Ark., July 12, 1892.

THE REQUIREMENTS FOR MEDICAL PRACTICE IN FRANCE.

To the Editor of the Medical Record.

Sir: An item in the Medical Record some time ago leads me to write concerning the legal regulations of medical practice in France. It was intimated that the tendency of French legislation is to prohibit the practice of medicine by foreign doctors in this country, and the writer spoke of retaliation in case of a continuation or enforcement of this rule.

Perhaps it would be well to examine the conditions that govern the medical profession in France, and then, knowing our subject, see if there is any injustice in them toward foreign applicants.

To understand fully the position of a medical school in this country, it must be remembered that the entire educational system of France is organized and administered by the state. The professional schools are the culmination of its liberal education; and consequently the student, commencing the alphabet in the public schools, mounts in grades through college, where he takes his bachelor degrees and continues his superior education under the direction of the state.

The doors of a medical school in France are closed to every candidate for "Doctor of Medicine" who cannot present his diploma of "Bachelor of Letters," and also of "Bachelor of Science," which give him the right to enter. The position of the state is that medical studies and subsequent practice call for preliminary ability and training, as a proof of which the above diplomas are exacted. The insistence of the best medical men in the United States upon the necessity of a higher standard of medical education endorses this position of the French Government.

The work of the medical school is divided into four years of forty weeks each.

The candidate for M.D. must therefore be provided with the degrees of B.L. and B.S.; must have followed regularly the lectures, demonstrations, dissections, laboratory exercises, and clinics for four complete years; have passed all examinations required in the course without a failure, and besides, must furnish certificates of two years' uninterrupted service in the hospitals, commenced *after* two years of medical study. No less than two hundred and eighty four days are accepted for each year. In addition, thirty days' service in the lying in hospitals, with a certificate for actual deliveries performed by the student are exacted for every candidate for M.D.

This amount of work carries a student over into his fifth year, when he is allowed to present himself for his final examinations, seven in number. After the successful completion of these, the candidate presents, publishes, and sustains a thesis, which gives him the coveted diploma. Few students are able to finish their medical studies in five years.

The state, indeed, requires much of the candidate before allowing the practice of medicine, but in return its diploma means a great deal. The doctor is the production of state education, therefore his duties are official and his protection is the state, from which comes his authority. It is in this spirit that the laws regulating the practice of medicine are enacted. Justice to the men who have accomplished the work required for M.D. here, demands that men who have done less work, or had a less costly and thorough education, be not allowed the same privileges without giving the same proofs of ability.

The following are extracts from the new laws passed by the Senate in March and April, 1892:

Article I. No one can practise medicine in France if he is not furnished with the diploma of M.D., delivered by the French Government in consequence of examinations undergone in a government institution of superior medical instruction.

Article II. No one can exercise the profession of dentist if not furnished with a diploma of M.D., or of

surgeon-dentist (D.S.). The diploma of D.S. will be delivered by the French Government after studies organized according to regulations given by advice of the Superior Council of Public Instruction, and after examinations undergone in a government institution for superior medical instruction.

ARTICLE III. Midwives can only practise their art of accouchement if they are provided with a diploma of first or second class delivered by the French Government after examinations undergone in a medical school.

A decree according to the advice of the Superior Council of Public Instruction will determine the conditions of previous training and the programme of study applicable for the candidates for midwifery.

ARTICLE IV. Midwives are forbidden to employ instruments or medicines without the presence of a doctor (exceptions provided for); but are authorized to vaccinate and revaccinate against the small-pox.

ARTICLE V. Doctors, surgeon-dentists, and midwives, provided with a foreign diploma, whatever may be their nationality, can only exercise their profession in France upon the condition of having obtained the diploma of M.D., D.S., or that of midwife, in accordance with the dispositions provided for in the preceding articles.

Certain dispensations from preliminary examinations can be accorded by the Minister of Public Instruction, in accordance with a regulation of the Superior Council of Public Instruction.

ARTICLE VII. Foreign students who present either the diploma of M.D. or of D.S., or pupils of foreign nationality who present a diploma of midwife of first or second class, are submitted to the same rules in regard to scholarship and examinations as the French students. Moreover, there can be accorded to them, in view of instruction in the faculties and medical schools, either the equivalent of the diploma or certificates obtained by them abroad; or the dispensation of the French grades required for this inscription, as also partial dispensations of scholarship corresponding to the duration of the studies completed by them abroad.

ARTICLE IX. Doctors of medicine, surgeon-dentists, and midwives are required to register, *without expense*, their title at the prefecture, sub-prefecture, or at the registry of the Civil Court of their district during the month which follows their establishment in the district.

A change of residence to another department involves a new registry of the title within the same period of time. Those who not having practised for two years, wish to recommence the exercise of their profession, must again register their title, under the same conditions.

It is forbidden to anyone to exercise the above professions under a pseudonym, under the penalty for illegal practice of medicine.

ARTICLE X. Every year in each district lists must be made out by the prefect or judicial authority; the said lists to bear the names, place of residence, and date and origin of the diploma of every doctor, surgeon-dentist, and midwife controlled by the present law.

These lists are posted during the month of January of each year in all of the counties of each district. Certified copies are transmitted to the Ministers of the Interior, of Public Instruction, and of Justice.

The statistics of the *personnel* of the medical profession in France and its colonies is drawn up every year under the care of the Minister of the Interior.

ARTICLE XV. The functions of medical expert in a court of law can only be filled by doctors of medicine of French nationality.

ARTICLE XVI. Every physician, health officer, and midwife is required, upon establishing the diagnosis, to declare to the public authority all cases of contagious disease under his observation.

ARTICLES XVII. to XXXVIII. determine the penalties for infringement of these laws, in fines varying from twenty to one thousand dollars, and in imprisonment from six days to one year, or temporary suspension from practice. Criminals cannot pursue the course of medical instruction, or if already in practice have their diplomas revoked, and can no longer practise their profession.

These laws go into effect one year after their enactment.

WILLIAM S. MAGILL, A.M.
26 RUE DUROC, PARIS, FRANCE.

Leprosy	0	0
Mumps	0	0

A Statue to Ricord.—The world owes a debt of gratitude to the man who, by his labors in the investigation of syphilitic diseases, confirmed (in 1838) Benjamin Bell's views (dating from 1793) as to the non-identity of gonorrhœa and syphilis. It was not to be expected that Ricord's name and fame would be allowed to remain unrecognized, and the Paris Municipal Council have authorized the placing of his statue on a spot in the Boulevard de Port-Royal, exactly fronting the Hôpital du Midi, the scene of his labors and teaching for thirty years. The statue, due to the chisel of M. Barrias, is now on view at the Salon. Its existence is due to the exertions of a committee who undertook the charge of a subscription raised by his pupils and friends. I last saw Ricord on the occasion of the funeral of Béclard, late Dean of the Faculty. He was then a decrepit old man, nearly bent double. Not very long after his own remains were escorted, with equal pomp, from his well known residence in the Rue de Tournon—a stone's throw from the Faculty—to their last resting-place. Some of his quaint sayings deserve to find a permanent place in treatises on the branch of medicine so intimately associated with his name. Who could forget that the lymphatic gland situated the nearest to a hard penile chancre was larger than the rest of the inguinal group, when he christened it "Le Préfet de l'Ain" (*aîne* = groin)? The atrophied remains of a syphilitic testis he wittily described as a "haricocèle," from its resemblance to a bean or pea. It is such little touches as these that reveal the good and successful teacher.—Cor. *London Lancet*.

THE NEW ROME AND THE QUESTION OF ROMAN FEVER.

BY EDMUND CHARLES WENDT, M.D.,

NEW YORK.

EVERY person of culture has probably, at one time or another, experienced a distinct desire to see Italy. And, indeed, what higher intellectual treat could well be provided than a holiday judiciously spent in that ancient land? That this is a mere truism is attested by the fact that, despite her reputation for insalubrity, thousands upon thousands of foreigners, year after year, continue to flock to Italy. It has almost come to be part of a liberal education to examine all her natural beauties, and to seek fresh inspiration by a study of those marvellous treasures pertaining to history, literature, science, and especially to art, which no other country possesses in like degree and number.

As for Rome itself, the eyes of the world have ever been directed toward the Eternal City. And this commanding position was freshly emphasized when, in 1870, the ancient town of Romulus became the capital of the new United Italy. Ever since then a distinctly modern life has been infused into the sluggish current of her existence. Even the outward appearance of the city has changed under the stimulus of a grand national revival. It is true the archæologist, the historian, the poet, and even the lover of art, have not looked on without dismay; for, although by no means completed, the process of modernization has already effaced many a cherished memento of the past, and thus robbed Rome of some of her ancient glory. Everywhere crumbling ruins and mouldy piles of dilapidated masonry have been replaced by those commonplace modern structures which the demands of a practical age have set up in all the larger towns of the civilized world. But sanitation is divorced from sentiment, and from a purely sanitary point of view there is surely nothing to regret in a transformation which substitutes healthful modern dwellings for the dangerous and scarcely habitable houses of by-gone centuries.

But quite apart from its permanent interest to all classes of men, Rome will soon receive the special attention of physicians, owing to the International Medical Congress which is to meet there in 1893. Under these circumstances some account of the city, from a medical point of view, may be of interest to the profession in America, more particularly as the bugbear of "Roman fever" is responsible for an exaggerated dread concerning the unhealthfulness of its climate, which most physicians share with the laity.

My personal observations and studies in Rome extended over a period of less than three weeks, and it is not pretended that they were at all exhaustive.

In fact, as will be seen later on in reference to several matters, and especially touching the vexed question of Roman fever, I have preferred to trust to the experience of able local authorities rather than to hazard opinions based on necessarily imperfect observations.

Of course, in some respects, a foreign physician may have a clearer judgment of local affairs than an old time resident. Yet one cannot expect to do justice to a large city, and certainly not to Rome, in the short space of a few weeks. I have, therefore, suppressed all except the most essential information.

Clean Streets.—The first thing that favorably impresses the stranger, especially if he happens to be a New Yorker, is that Rome is a clean city. There are few wide streets, except in the essentially new quarters, and the paving is far from good. Nevertheless, the admirable cleanliness of even the smaller and less important avenues shows that an efficient system of street cleaning and garbage removal is now in force. New York has much to learn from Rome in this matter.

Disgusting Public Urinals.—But in spite of clean streets disagreeable odors are far more frequent than they have any right to be. These odors for the most part arise from the public urinals, which everywhere disgracefully obtrude their obnoxious presence upon normal eyes and nostrils. The Romans have the most frank and astonishing disregard of the common proprieties of civilized life, in the matter of relieving themselves of their surplus renal secretion, which it is possible to imagine. And I may remark in passing, that the same indecency is found repeated in all the principal Italian cities, with the single exception of Milan. In almost every side street, and usually but a few steps beyond the teeming thoroughfares, these countless urinals have been introduced. With few exceptions they are malodorous, disgusting, public nuisances. Fancy wedge-shaped shallow clefts sunk into the walls of the houses and unprovided with even the pretence of a covered approach. It seems incredible that such barbarous stench-breeders should be allowed to remain in a large modern town, where civic pride is not altogether unknown. I can account for the anomaly only on ethnological grounds, the Latin view of public decency being a much broader one than prevails in Anglo-Saxon lands.

Purity and Abundance of the Drinking-water.—Turning next to the water-supply of the city, a very satisfactory state of affairs is found to exist. For the drinking-water of Rome is clear, pure, and tasteless. It is supplied in practical over-abundance, and is without doubt a potent factor in maintaining the present standard of health of the city. The water is conducted in several well built aqueducts, the sources of supply being located miles away from the city. The water is rather hard, however, and while the natives and residents take it with impunity, a stranger may experience some temporary discomfort during his period of acclimatization. The chief aqueducts running into Rome[1] are *la Vergine*, *la Felice*, *la Paola*, and *la Marcia*. Among the minor sources of supply are the *Sallustiane*, *Argentina*, *Api*, *San Damaso*, *Grillo*, *San Felice*, *del Sole*, *la Lancisiana*, and *l'Innocenziana*. But these waters include those of the entire "*Comune di Roma*," although I have not mentioned all of them.

It is unnecessary to present a detailed account of the chemical analysis of these waters. It has been found that, barring the hardness already alluded to, there is no ground for complaint.

Bacteriological examinations were also made by Professor A. Celli, of the Institute of Hygiene of the University of Rome.[2] The results were in the main satisfactory. But some of the local suburban waters were found to be suspicious, and certain well-waters were pronounced decidedly impure. All such waters have been, or will be, entirely suppressed. All the subsoil waters were, however, found to be germ-laden.

[1] Risultati dell' Inchiesta sulle condizioni igieniche e sanitarie. Roma, 1886.

[2] Bolletino della Com. speciale d' igiene del municipio di Roma.

To give some idea of the quantity of potable water now carried into Rome, the following figures may be adduced. In twenty-four hours the Vergine supplies 80,000 cubic metres, the Paola, 40,000, the Marcia, 108,000. Moreover, the authorities state that these quantities could be easily doubled, so that for all time to come an abundance of unimpeachable drinking water is assured to the citizens.

Drainage Imperfections.—Hundreds of fountains play day and night in Rome, and one would naturally suppose that with all this enormous flow of water the drainage problem would have been satisfactorily solved there long ago. This is not the case, however, and in the matter of sewage disposal, and especially in all that relates to sanitary house fixtures, Rome is still far behind the age, if the best Anglo-American standard is used for comparison.

Mr. W. J. Stillman, the able correspondent of the London *Times*, who kindly placed at my disposal much valuable information culled during his thirty years' residence in Italy, has indeed assured me that cesspools no longer exist in Rome, and that the drainage of the town now approaches perfection. But with all due deference to his ripe experience in sanitary matters, I must emphatically dissent from so optimistic a view of the present condition of Rome. Much has been done since the authorities have busied themselves with this vital sanitary problem, and to an old resident the changes will naturally appear very great. But the new-comer cannot avoid observing that much more remains to be done.

The new Tiber embankment, when completed, will doubtless be a long step in the right direction. But what Rome needs above everything else is a complete reformation of her system of house plumbing, including the proper ventilation of soil-pipes, the introduction of traps, the disconnection of house-pipes from main drains by modern methods—in a word, the radical transformation of present arrangements.

It is quite true that many of the better class of hotels and dwelling-houses are now supplied with clean-looking, modern English cabinets, which apparently answer every hygienic requirement. But the Roman sanitary engineers have not yet learned that more than this "surface trimming" is needed to reform obsolete house-drainage methods.

As for the absence of cesspools, I will at once admit that such dangerous old pits as are found in Florence and elsewhere, I have not personally discovered in Rome. But many houses have square receptacles situated in the courtyard, which appeared to me to be cunningly contrived breeders of noxious stenches, while immense pipes (in some instances of such ample calibre as to admit the body of a man) very successfully convey foul gases to the apartments of the residents. It is alleged that these receptacles are frequently emptied and cleansed, and that they really serve as cut-offs from the main sewers. I can only say that those boxes which I inspected were actual receptacles of filth, that ought not to have been allowed to accumulate for a single hour of the day. Moreover, in spite of the abundance of water, the flushing arrangements are often primitive, and the water is thus needlessly wasted. Evidently a little English missionary work in the direction of enforcing the introduction of sanitary plumbing would not be wasted in Rome. Eight years ago Mr. Hart wrote in the *British Medical Journal* as follows:

"Most of the best and newest hotels are indeed provided with excellent cabinet fittings, but this is delusive and incomplete unless the ventilation and disconnection of the soil-pipes are carried out. This is the more important in Rome, because the main sewers are mostly of a labyrinthine character and Brobdignagian proportions. In some places they are connected with the vast ancient cloacæ, and it is certain, from their form and size, that they must be very largely elongated cesspools of deposit rather than sewers of transit. Under these circumstances it is conceivable that the more modern and complete domestic arrangements for water-carriage adopted in the hotels become sources of danger, by providing also for a more abundant reflux of sewer-gas, which the heating of the corridors sucks into the atmosphere and disperses throughout the building."

These criticisms apply to-day with even greater force than they did in 1884, owing to the large increase of population.

Rome's sewage is discharged into the Tiber, and the numerous evils incident to floods or an abnormal lowness of the river water will be done away with when the really fine granite embankments are completed. It is to be hoped that the financial straits of the Italian Government will not seriously hamper the completion of this necessary, though costly, undertaking.

Health, Disease, and Mortality.—In spite of the imperfection of its drainage system, and a still excessive mortality from malarial diseases, Rome is at present the healthiest city in Italy, and one of the healthiest cities in all Europe. This surprising statement is not based merely on the concurrent testimony of the leading physicians of Rome. It is clearly shown by a study of the bulky but eminently trustworthy Government reports. From the *Annuario Statistico di Roma*, published in 1890, the following tables have been compiled. For purposes of ready comparison the death-rate of the principal Italian towns is placed side by side with that of other European cities. (St. Petersburg is also included in the table.)

General Death-rate per 1,000 of Italian and Foreign Cities.

Italian cities.	1885.	1886.	Foreign cities.	1885.	1886.
Rome	23.6	20.0	Buda-Pesth	29.4	39.4
Padua	27.6	37.4	Marseilles	39.0	35.0
Bologna	27.3	32.6	St. Petersburg	28.9	30.6
Venice	31.6	32.6	Hamburg	26.0	29.3
Verona	28.1	31.9	Vienna	27.9	26.2
Genoa	27.1	30.1	Berlin	24.8	25.8
Naples	28.5	29.6	Paris	23.6	24.6
Milan	29.1	29.5	Liverpool	23.7	23.7
Florence	27.0	28.6	Amsterdam	24.0	23.6
Turin	25.4	24.6	Copenhagen	20.7	23.2
Leghorn	22.2	25.9	Lyons	23.3	23.0
Messina	29.8	23.9	Brussels	21.6	22.9
Palermo	36.7	20.5	London	17.1	19.8

Italian Lack of Sanitation.—That Italian lack of sanitation is still responsible for many unnecessary deaths cannot be seriously questioned. And it is all the more creditable to Rome, therefore, that in spite of the negligence of the ignorant masses, a material improvement has of late years become manifest in the general health of the city.

A glance at the following table will show the deplorable loss of life from zymotic and paludal diseases for the kingdom at large. It is made all the more apparent by comparison with England and Wales, these countries having a population about equalling that of Italy.

The figures are for one year only, viz., 1887.[1] But they are more eloquent than words.

Number of Deaths Resulting from Various Diseases in Italy and England.

Disease.	Italy.	England and Wales.
Scarlet fever	14,631	7,859
Diphtheria and Croup	28,273	8,422
Typhoid fever	27,273	5,662
Malarial fever	21,033	193
Cholera	8,150	462
Small-pox	16,219	506

In place of lengthy descriptions of the occurrence of diseases and their seasonal prevalence, the subjoined

[1] See Nineteenth Century, March, 1892. Article *Italia non fara da se.*

tables may be profitably studied. A glance will show that Rome is at its worst during the very time when it is most crowded with foreign visitors and tourists. But fashion has ever been a more formidable power than mere health.

Table Showing Number of Deaths from Principal Diseases (except Malaria) at Rome.

	Typhoid fever.	Small-pox.	Contagious pneumonia and acute catarrh.	Other diseases of the respiratory organs.	Diphtheria.	Malarial fevers and chronic affections from malaria.	Enteritis, diarrhœa, indigestion. Cholera.

Fatal Malaria.—To the courtesy of Mr. W. J. Stillman I owe the compilation of the following painfully instructive figures, showing that while the mortality from malaria is on the decrease in Rome, it is still decidedly high. The significance of this table is enhanced when it is remembered that the population of the commune of Rome has risen rapidly from about 280,000 in 1881, to something like 450,000 in 1891.

Thus there is observable in this period an actual decrease of malaria, which, taken in conjunction with the growth of population, is to some extent reassuring as to the future of Rome in this particular.

And further, it is only fair to state that the suburban population is much more responsible for this mortality than the dwellers in the city. The malarial peasant invariably goes to Rome to die, even if he took the fever scores of miles away. It is this influx of outsiders that helps to swell the death-rate of the city, and may lead to erroneous conclusions.

Roman Fever.—Turning now to the important question of "fever," I found fewer differences of opinion among the physicians of Rome than I had anticipated. Indeed, there is a singular unanimity of judgment among local medical men on this point, namely, that the danger from Roman fever has been grossly exaggerated. Serious illness is indeed often invited by the neglect on the part of swarming tourists of ordinary prudence. And for some occult reason every departure from health occurring in visitors of the Eternal City is by them promptly labelled "fever." But while Rome is not in any sense a health-resort, as it was once held to be, I am convinced that the city is not a more dangerous place of residence than Paris, or Berlin, or Vienna, or, for that matter, than New York.

Owing to the importance of this subject and the many misleading statements often found in print, I believe the following views, kindly expressed to me in writing by Dr. Charles, of Rome, will be read with interest by American physicians. It will not be out of place to state here that Dr. T. Edmonston Charles has had a very wide experience, both as a practitioner and lecturer, in India, in France, and of late years in Rome, where he now occupies the official positions of physician to the British Embassy, and of honorary physician to the Queen. In answer to my questions, Dr. Charles writes: "Tradition has it that when he had to write an article to order on the snakes of Iceland, the writer, after boldly commencing by the statement, 'There are no snakes in Iceland,' ran short of ideas on the subject. You ask me what is Roman fever. But here the similarity of our positions ceases, for there yet remains much to be said on the subject, and you can easily understand that your question will require a longer answer than you might at first have imagined. It may seem a paradox to affirm that there is no Roman fever, when all are aware that there is no article of faith more generally held, and certainly none more firmly clung to, than that Roman fever is very fatal, and that it is very common. Everybody knows this, so what is the use of denying it? I confess I think there is very little to be gained by running counter to such a widely diffused delusion. *Populus vult decipi; decipiatur.* As soon would I attempt to persuade a member of the Psychological Society that ghosts do not walk, or an aged Scotch crone that the Banshee exists only in her imagination, as to argue the question of Roman fever with an ordinary tourist. I cannot pretend to be able to give a complete explanation of the origins of a faith which has succeeded in dominating so many minds, but the poverty of the Italian vernacular in regard to illness, seems to have been at the root of a good deal of the misconception.

"The uneducated Italian, when he feels ill, has but one way of expressing himself, '*che febre*,' or '*ho la febre*.' Now, place yourself in the position of receiving the same answer every time you made inquiries about a trivial indisposition of a servant, an artisan, or a mechanic—and this, be it remembered, whether he suffered from a toothache, a cold, a bilious attack, nay, even a fit of idleness—and consider how long it would take you to arrive at the conclusion that you were living in a very feverish country. From this it is but a short step to begin to calculate how long it will be before you yourself are attacked; and on the first symptoms of any trivial illness appearing, to believe that your own time has come, and that you are already in the grip of this all-devouring monster. The staple article of conversation among certain classes of visitors to Rome is about that haunting spectre, the Roman fever. It is a subject that seems inexhaustible, and from its having a terribly personal significance, it possesses a fascination far beyond the glorious pile of St. Peter's, or the classical ruins in the Roman Forum. Such being the case, it not only affords occupation to the thoughts during the waking hours, but intrudes itself into the dreams of the night. Some brains cannot long resist the strain. From fearing to get it, they fear they have it. One of the painful experiences entailed by a practice in Rome consists in meeting with people who, though phy-

sically well, are mentally ill, having worried themselves into believing that they are already the victims of this dread malady. I have seen people (otherwise very intelligent) who, with a common cold, or some very simple ailment, or perhaps only tired with a long journey to Rome, have sent for me on the day after their arrival, and in beseeching tones implored me to tell them if I thought they had Roman fever, as they would not stay a day longer in the place, but would clear out by the evening train. It is lamentable to attempt to estimate the sum of human misery caused by such a widely spread belief.

"No one gains by being an apostle of this false creed, and yet no missionaries are more zealous than its votaries, and no faith is so well supplied with a never-ceasing flow of converts to it. Medical men come by hundreds to Rome. How many of them have seen a case of any kind of fever in Rome, and yet how few of them could say boldly that they did not believe in Roman fever?

"In the sense in which you ask me, I have seen only three fevers in Rome: 1, malarial; 2, typhoid; 3, febris communis continua. You may, if you like, call one or all of these Roman fevers, only if you do so you lodge yourself in the awkward predicament of finding exactly the same fevers in America, in the persons of people who have never been in Rome, or have even never crossed the Atlantic. In the above enumeration I have purposely omitted febricula, as it manifestly has no bearing on your question. Let me say a few words of explanation about each of these three fevers, as from what you say I gather that American physicians would like some positive information regarding them.

"1. **Malarial Fever.**—Though I am here from the middle of October to the end of June, I have never seen a case of malarial fever caught in Europe, in any American or Englishman. I doubt very much whether they could have caught a malarial fever in Rome even in the months in which I am not here. But of this I am certain, that no one has consulted me with either a quotidian, tertian, quartan, or any other form of malarial fever contracted in Rome, or, as I said before, in Italy. In Americans I have only seen minor manifestations of the malarial poison, and in every case the sufferers have assured me that they were only too familiar with their symptoms from their American experience. Circumstances bring my way numbers of aristocratic and moneyed classes of Englishmen. It is among these classes that sportsmen are to be found, and hence all the malarial fevers I have seen in Rome have been contracted in shooting excursions in India, Southern Africa, Algeria, or elsewhere. Since Laveran wrote and Marchiafava labored, and Osler, of the Johns Hopkins University, taught, the word malaria has come to occupy a very subordinate place in the causation of fever in Rome. Even now, however, the word is much too loosely used. It is far too convenient a cloak for our ignorance to be lightly laid aside, too easy a subterfuge to be easily taken from us. Patients do not like being told that we do not know what trifling indiscretion has made them feel ill, but they do like having it laid down that malaria is at the root of their trouble. Such being the case, it is too much to expect of human nature—just yet—that a medical man will allow himself to be badgered about a case when he can see so easy a way out of his difficulty. Or, to take a higher view of the position, there are many medical men who for a lifetime have been persuading their patients that they had some malarial element in their case, and they have made the statement so often that they believe it implicitly themselves, and cannot be got to understand that they may be wrong, and that an error, however often repeated, can never come to be the truth. Even here, however, perhaps it would be well if they realized that their position is rendered distinctly untenable by the fact that they have never sent a specimen of malarial blood to a pathological laboratory to have the correctness of their diagnosis disproved, and have never moved a finger to try and confirm their diagnosis by an appeal to their own microscopes.

"There are many thoughtful and highly educated medical men in Rome who live on the traditions of the past, and from having seen a little, and heard much, of malarial fever in Rome, would be staggered if it were pointed out to them that for the last ten years they have not seen a single case of quotidian, tertian, or quartan fever. Nor is the explanation of this hard to seek. The Rome in which they gathered up their experience of malaria is not the Rome of to-day. In the city of twenty years ago large districts were unbuilt over and were consequently undrained, and formed choice habitats for the malarial poison to be generated. Since Italy chose it for its capital, all this has been changed. Any low swamp, garden, or vineyard has become a valuable possession as a building-site. Long lines of well paved and carefully drained streets cover the picturesque haunts where malaria so long lingered; and it would be difficult for an investigator to obtain a list of possible places where he might reasonably search for malaria inside the city walls. The uninhabited slopes of the Janiculum hill is the only place I know of where I would not like to sleep at night in the malarial months of August and September. This, though technically in the city from being within the walls, is far removed from the Rome inhabited by visitors, and lies on the other side of the Tiber. Malaria requires for its development intense sun heat and a certain amount of moisture. Ground built over by barracks and palaces, with all its surface moisture and subsoil water drawn off into a fine net work of well-laid drains, no longer fulfils the conditions required for producing malaria. A well-cultivated patch of garden in a few years is equally free from danger. This is why a student of malaria is now driven outside the walls of the Italian capital if he wishes to make researches on this subject.

"2. **Typhoid Fever.**—We have typhoid fever at Rome as you have it elsewhere, only not so much of it. We have nearly as good a record as they have in London, and the death-rate from this disease is consequently a far more favorable one than can be shown in Berlin, Vienna, and Paris. In fact, this exemption from typhoid has always seemed to me very remarkable. I believe it can be traced to two circumstances: to an abundant and excellent water-supply, and to well-flushed and consequently well-emptied sewers. Some of our hotels are fairly well disconnected from the sewers, and in other respects have had a good deal of money expended in their sanitary plumbing; but I am unable to attribute much influence to this, as the immunity from typhoid extends to the general population, who are as badly off in this respect as they can well be. The late Dr. Aitken, whom I succeeded in practice, told me he had seldom seen a case of typhoid contracted in Rome. I can add my testimony to his, and as our united experience covers about a quarter of a century, it is not without its value. When anyone asks me about their danger of contracting typhoid during their residence here, I have but one answer for them. 'I cannot pronounce you safe till you have been fourteen days here, but as soon as this period of probation is over, your danger of contracting this disease during all the rest of your stay in Rome is infinitesimal, so you may stay here for ten years if you like.' The reason for my excluding the preliminary two weeks is a simple one. The incubation period for typhoid being of this duration, anyone having imbibed the poison, even on the day before his arrival, may develop it in Rome from having brought it with him. This, perhaps, is the place to say a few words regarding these cases of imported typhoid. Up till quite recently they formed a very considerable part of an English medical man's work in Rome. In fact his year's income depended very much on the number of such cases that came into his hands. Cases came from elsewhere also, but a constant stream flowed from Naples. After the late terrible experiences from cholera in that city, their disgraceful water-supply was changed. Now their

drinking-water is abundant and pure, and their typhoid death-rate has gone down. During all the years I have been in practice in Rome I have not seen a single case of typhoid brought from any of the hotels of Naples situated high up above the sea. After this digression about typhoid cases imported into Rome, I now return to those cases for which we are ourselves responsible. In my own practice, as distinct from cases I have seen in consultation with my *confrères*, I have not yet met with a single case among the travelling public, in any American or Englishman, which was contracted in Rome. Among the residents I have attended one French servant and one English servant in whom the disease was distinctly due to local influences. In the practice of my friends I have only been able to recall two, or perhaps three, cases that have contracted the disease here. I have before me the records of all the burials of American Protestants in the cemetery in Rome from June 1, 1881, to May 31, 1891 — that is, for a complete ten-year period. In it I find only five deaths that can with an approach to certainty be traced to typhoid. That is an average of one death in two years. Besides this, there have been other two deaths from fever, one returned as febris subcontinua, the other as perniciosa. It is open to anyone to regard those as possible deaths from typhoid, but I prefer to class them as deaths from the next fever that I shall presently have to refer to. Even, however, throwing them into the typhoid account, they do not raise the average risk that an American has run during the last ten years of dying from typhoid in Rome to any very alarming figure, and, when contrasted with the popular beliefs on this point, ought to tranquillize the medical mind, and through it to allay the apprehensions of the lay members of the multitudes that flock every winter to Rome.

"**Febris Communis Continua.**—Simple continued fever, though appearing in the nosologies of English, Americans, French, Germans, and Italians, has not yet attracted the attention that it deserves. Its natural history has still to be written, and yet it is a most important disease. Murchison in his great classical work alludes to it. All are agreed that it is independent of any specific poison. The primary part affected seems to be the nervous system. Murchison says 'the best illustration is to be found in the fever that occasionally results from sheer nervous exhaustion consequent on mental or bodily fatigue.' He also traces cases to exposure to the sun, and surfeit. Many of the cases that I have seen have been evidently traceable to entering a cold building when the body was overheated.

"Early in my career in Rome I came to speak of it as chill fever. It is very difficult to get a patient who is seriously ill to understand the position when he hears you talk of simple fever or common continued fever. As often as not they tell you they never heard of chill fever, but, having experienced the chill and being convinced they have fever, they accept the designation as something intelligible. As a rule, however, my cases have borne out Murchison's dictum as regards nervous exhaustion. Many of them have been fagged out with days of excessive sight seeing before getting heated in the sun, and then entering a cold church or museum. Again, a long day's picnic in the country—say at Tivoli or Frascati—miles of walking, far beyond their powers, and hanging about for hours, seeing classical ruins, with nothing but a biscuit or other imperfect refreshment; then—always when tired out and heated—a wait as the sun went down in a draughty station, a keen north wind, and no extra clothing to protect themselves, an hour or two in a cheerless, draughty, railway train, and you have another sure prescription to get an attack of the fever we are considering. To see this fever in its full force, go to any country with a great daily range of temperature. A hot sun during the day and a cold wind at night. The Malta fever is one prominent example of it; the Bengal remittent, as seen in Calcutta during the cold-weather season, is another. But instances of this fever may by met with everywhere—in New York, London, Berlin, and Paris. In Rome it has disturbed us much in our diagnosis. On the one hand it may make us think we may have a malarial remittent to deal with, and on the other may make us believe that we are treating a typhoid. If we have a succession of cases, however, that we look on as malarial, we very soon persuade ourselves that quinine is of no use in malaria, as this fever goes on in spite of the largest doses of quinine. In the early stages, though it may depress the temperature a little, it does not bring the fever to an end. When, however, the fever is near its end, and the temperature is very little over normal, a little quinine comes to have its place.

"If you label these cases typhoid you come to have no belief in the diarrhœa-specific eruption, or classical range of temperature connected with typhoid, and if, in addition, you, like the German, begin your treatment with a dose of calomel, or, like the French, with an emetic, you soon convince yourself that you have discovered the secret of cutting short your typhoids, as you see many cases ending before three weeks, and not a few between ten days and a fortnight. Abortive typhoids become the rule, a rich experience in such cases is soon gained, if you only diagnose cases of common continued fever as typhoid. This fever can hardly be traced in the death-rate. It is registered either as a malarial remittent or as a typhoid, according to the view taken of it by the medical attendant. In referring to the typhoid mortality among Americans I had occasion to allude to two cases which from the way they appeared in the registers you might choose to regard in the light of typhoids. I may also now say that one or more of the deaths registered under the head of typhoid may possibly have been due to the fever I am now writing about. From the point of view of 'Roman fever,' it does not much matter of what fever the person is believed to have died. It is important, however, that the true fever-rate is known. And on this point there can only be one doubt. No one can be very sure that the case registered as perniciosa was a fever at all. It possibly was a sudden death from apoplexy or heart disease. The mistake, however, if there is one, is on the side of overstating the fever mortality. I believe no cases of fever have been registered under any other head. These seven cases of fever form the most important group of deaths. Then follow four deaths under the heading of morbus cordis, and three under the heading of pneumonia. These account for four and three deaths respectively. The cause of one death is not recorded, and eight deaths are due to cancer, diabetes, anæmia, gangrene of the mouth, peritonitis, laryngitis, consumption, and meningitis. These twenty-three deaths are all that have taken place among the American Protestants living in Rome during the ten years I have referred to. The deaths among the Roman Catholic Americans cannot be procured.

"As the great majority of travelling Americans are Protestants, these figures may be relied on as giving a very correct idea of what the Americans who have died in Rome owe their deaths to. This record speaks for itself. That only twenty-three Protestant Americans have been buried in the cemetery in Rome during ten years, must be a revelation to most people. During this time the number of Protestant Americans who have visited Rome has been very large—how large no one can say with any approach to certainty. I will not allow myself to hazard any attempt at an exact statement of numbers, but I will say, without fear of contradiction, that if you want to represent in figures such a multitude, you cannot do so in either hundreds or thousands, but will have to number them by the hundred thousand.

"I have previously made the statement that malarial fevers do not kill Americans in Rome, also that deaths from typhoid have been much reduced in frequency. Building, drainage, water-supply, have conduced to this happy result. The growth of the city, accident, and design have led to this being done for the travelling public.

In other words, the community has diminished the death-rate from these two of the fevers alluded to. As far as my knowledge goes, they cannot do anything to lessen the dangers of the third fever. But what the community cannot do, the individual can. If everyone who comes to Rome is impressed with the idea that it is more or less his own fault if he gets attacked with chill fever, doubtless the frequency of such attacks will be much lessened. To be forewarned is to be forearmed. So let everyone avoid depressing his nervous system by cruel over-fatigue, and let him be careful never to enter a cold edifice when overheated. Cab fares in Europe are very cheap. For less than a quarter dollar two persons can drive from one end of the city to the other. The physical exertion of standing about sight-seeing for hours is quite enough of strain on the nervous system without the needless exertion of walking for miles to reach the point you wish to arrive at. When entering a cold place, put on an extra top-coat or cloak or shawl, a jacket, or what not. When sight-seeing, also make a point of securing a good mid day meal. With these precautions you are safe. Those who cannot afford a cab fare, or who will disregard the other necessary precautions, will best consult their true interests by remaining safely at home."

To this description of "fever at Rome," by Dr. Charles, I have nothing to add, except to repeat that natives do die of malaria in and around the Italian capital, even if foreigners are not apt to suffer in the same way.

It would be easy, of course, to give some account of the preliminary organization, now well under way, of the International Medical Congress, also to speak of medical instruction at the University of Rome, of the great hospitals of the city, of recent medical legislation, of the peculiarities of practice, the income of professional men, and many other matters likely to interest physicians. But, as already intimated, my object was not to write exhaustively, but rather to present certain points touching what I conceived to be essentials, in a succinct yet accurate manner. I trust that, with the co-operation of Dr. Charles, this may have been accomplished.

THE SENSORY-MOTOR FUNCTIONS OF THE BRAIN.

By L. HARRISON METTLER, A.M., M.D.,

CHICAGO, ILL.

THERE seem to be nationalities in science as well as in statecraft. In a general way it may be said that the English-speaking physiologists regard the sensory and motor areas of the brain as separate and distinct, and that they look upon them as the centres for the direct reception and emission of sensory and motor impulses. The Germans favor the view that these areas are the centres for the direct reception and emission of nervous impulses, but they hold that they coincide or are more or less intermingled. The French and Italian investigators study the question more from the psychological standpoint, and place less stress upon the separation or commingling of the sensori-motor areas than they do upon the doctrine that the cortex is a general centre for the representation of motor and sensory images. Psychosis, according to them, is a sensori-motor phenomenon, and mentalization the result of the combined activities of the cortical sensory and motor areas. The direct sensori-motor elements are lower down than the cortex. Impulses of cerebral origin are as much peripheral as those starting from the skin. Voluntary action is as much a reflex as an ordinary involuntary spinal reflex. This is a mere outline statement of the three theories now in vogue in regard to the sensori-motor areas of the basin. For the doctrines of the Italian school I must acknowledge my indebtedness to the work of M. Jules Soury, "Les Fonctions du Cerveau," whose account I have made ample use of. The teachings of the English and German physiologists are more familiar than those of the Italians to the average American reader. The views which I will venture to advance in the latter part of this essay tend somewhat, though not entirely, toward the Italian doctrines.

It is much to be regretted that patients presenting symptoms of a lesion in the motor zone of the cortex are not more frequently and minutely examined with regard to general sensation. In many of the reported cases of paralysis there is no mention whatever of sensation; and in others, where the attempt has been made to discover the sensibility of the skin, the methods adopted have been so crude and unscientific, and the results obtained so meagre and indefinite, that the report, in this respect at least, is almost valueless. In comparison with the motor tests for the localization of a cortical lesion, sensory tests will probably always remain less popular. The variation of the personal equation alone is enough to shake one's reliance on sensory symptoms, and to properly perform these tests necessitates an unusual amount of patience, shrewdness, and insight into human nature. The instruments of precision must be employed in every conceivable manner, and frequently at most unexpected moments. Unlike the testing for paralysis, we are here dependent almost absolutely upon the patient and his subjective feelings; hence we must study closely the patient's peculiar temperament and make due allowances for his intellectual status. His entire physical condition must at the same time be taken into consideration, for if there be paresis, for instance, a sensory response may be very greatly modified by the inability of the muscles to act and manifest the appropriate motor response. Notwithstanding all these difficulties it is extremely desirable that every case of paralysis be carefully and accurately tested for general sensation. The experiments of the laboratory favor the view that the sensory areas of the cortex are separate and distinct from the motor, while clinico-pathological data intimate that they are identical, or at least partly coincident. Which is the true condition can only be settled by the most rigid physiological and pathological observation.

In regard to the centres for cutaneous sensations—touch, pain, temperature, and the sensation commonly known as the "muscular sense"—many theories have been advanced. The general consensus of opinion holds that the optic thalamus is the basal ganglion for the reception of sensory impulses from the outer world. Luys, Ferrier, von Monakow, Fournier, and Crichton-Brown so teach; though Flourens, Longet, Tamburini, and Schiff attribute motor functions to this ganglion. Above the thalamus the fibres radiate through the corona and terminate chiefly in the cortex of the parietal and temporo-sphenoidal lobes. Below the thalamus the sensory are clearly distinguishable from the motor paths. Do these so unite or intermingle above this ganglion as to terminate in the same cortical area, or do they still remain apart, one set (motor) going to the central lobes, the other set (sensory) turning back to end in the postero-parietal lobes?

In his earlier experiments Ferrier found that injury to the hippocampal convolution and cornu ammonis produced loss of tactile sensibility on the opposite side of the body. He therefore located the centre for tactile sensibility in the region of the hippocampus. This was confirmed by Yeo in his experiments on monkeys in 1884. Horsley and Schäfer have extended the views of Ferrier, and as a result of their investigations concluded that the whole of the limbic lobe (including the callosal and hippocampal regions) presided over the sensations of touch and pain, if not exclusively, at least to a very large extent. In some of their experiments the loss of sensation was accompanied by motor phenomena, which they attributed to unintentional injury of the motor area during the performance of the operation. As opposed to Munk and Schiff, who would possibly argue from this the identity, in part at least, of the motor and sensory areas, they state that in some of their experiments there was paresis

of the lower limbs with anæsthesia of the upper limbs, and in others anæsthesia without paralysis.

There seems to be some very intimate connection between the limbic lobe and central lobules, for when we remember how frequently sensory auræ and other paræsthesiæ precede and accompany Jacksonian symptoms caused by a limited lesion of the motor cortex, we must admit, if not the identity, at least the extreme intimacy of the motor and sensory areas. Many of these focal lesions do not extend deep enough to involve the radiating fibres from the sensory areas, and their mutual influence must, therefore, be entirely cellular and transmitted from one to the other by associating fibres.

This influence may be of an inhibitory nature, for clinically the anæsthesia accompanying such forms of local paralysis is never complete, but is rather of the inhibitory type Brown-Séquard has given special attention to the extensive inhibitory functions of the nervous system, and in the light of his investigations such an explanation is not unwarrantable. If the sensory and motor areas were identical, it is hard to comprehend how a limited focal lesion could give rise to complete paralysis and incomplete anæsthesia in related parts of the body. Both sets of cortical cells would, presumably, be similarly injured, and the anæsthesia would be more or less proportionate to the amount of paralysis. Ferrier's objection to the experiments of Munk and his followers, in this connection, seems to me to be a weak one when he states that in animals the loss of sensation is only apparent and not real, because the paralyzed animal is unable to express any sensation. This may do for animals, but in man there is an abundance of clinical observation which goes to show that there is frequent loss of sensation with Jacksonian symptoms.

The sensorial area is thus made to include the gyrus fornicatus, hippocampal convolution, procuneus, and portions of the parietal convolutions. In a general way it may be stated as the postero-parietal parts of the hemispheres. This arrangement seems to be established by pathological observations in man, as well as by experimental investigations upon the lower animals. It must not be forgotten, however, that Ferrier's observations were made mostly upon the lower animals, and that the focal epilepsies, which finally terminate in general convulsions, reveal a higher and more intricate structure of the human brain.

Those who maintain that the histological structure of the central convolutions affords a clue to their proper functions reason beyond the facts. Thus Gowers says "it is instructive to note that in this part are found the largest ganglion cells met with in the cortex, cells comparable to, though exceeding in size, the certainly motor-cells of the anterior cornu of the spinal cord." Nevertheless we find in the histological structure of the hippocampal convolution, which is admittedly sensory in function, pyramidal cells very similar to those of the motor areas. They lie just beyond what is known as the stratum radiatum. Furthermore, these large cells have never yet been proved to be strictly motor. They may be muscular, meaning by that term that they are in immediate connection with the muscular apparatus, and are therefore capable of a grosser or more vigorous form of activity than the delicate receptive sensory cells. But when we remember that sensation itself is but a mode of motion we can understand that these giant-cells may differ from the smaller ones not so much in kind as in degree. The reflex character of most of the sensori-motor phenomena would seem to indicate that both sets of cells possessed the faculty of receiving and emitting nervous impulses and it is hard to escape the conclusion that the real differences in their functions are dependent more upon the nature of the terminal end-organs, with which they are connected, than upon their own particular structure. Physicists believe that all phenomena are but the expression of a form of motion. Light, heat, electricity, are but different modes of molecular motion. Nervous activity has often been likened to electricity; but whether the comparison be true or not, it is more than probable that the former is as much a mode of motion as the latter. Both sensory and motor phenomena are alike the result of molecular movements. The muscular contractions are doubtless the direct expression of the molecular changes within the muscular tissues and the reflex circle, beginning in a peripheral irritation, running through the centre from sensory to motor cells, and finally passing out again to terminate in gross muscular contractions, is simply the transmission of the same molecular disturbance, differing in degree, but not in kind, in the various parts of the arc. In a rough way it may be compared to a taut string which experiences throughout its entire curve a gentle vibration started at either extremity.

The most positive knowledge we possess in regard to the functions of the cortex is that the central convolutions somehow preside over the movements of the body. And yet, as Gowers says, "we need not conceive that these parts subserve no other function (we shall presently see reason for believing that they have sensory as well as motor functions)." Injury to these convolutions produces spasm or paralysis, and, so far as we know, these symptoms are not produced by cortical lesions outside of these convolutions and their immediate neighborhood. That these are not the only centres that preside over voluntary motion is to be inferred from many experiments upon animals. A rabbit whose entire cerebrum has been removed can still run; and, according to Goltz,[1] there was no complete paralysis, but only a slight anæsthesia, observed in a dog whose whole brain except one occipito-parietal lobe was excised.

It is an old-established fact that removal of the cerebral hemispheres, olfactory ganglia, optic lobes, corpora striata, and optic thalami does not result in the loss of voluntary motion and general sensibility. There is loss of intelligence, of inhibitory rationality; but the animal still executes purposive movements which are quite different from the simple reflex acts depending upon the spinal cord. Hence the question arises, What is the nature of these disturbances of voluntary motion caused by destruction of the cortical motor areas? A dog deprived of his two sigmoid gyri does not manifest motor paralysis, if by that term is meant absolute loss of motility. There is not a single physiologist who maintains such a thesis; hence the ground for the criticisms of Goltz, the distinguished opponent of the localization theories. The cortical motor areas must therefore preside in some special way over the muscular apparatus, and not directly, as at first seemed to be the case. In 1876 Hitzig spoke of the effects of cortical lesions in the motor area as "the expression of an abnormal representative action;" in other words, as the result of a destruction of the motor images belonging to certain voluntary movements. The muscles of the animal are not paralyzed, but the animal no longer possesses any mental images or ideal representations of the movements it should make or desires to make. The condition is probably somewhat like that of the nightmare, in which the sufferer is more or less conscious of his surroundings and is full of a desire to move, but is incapable of action, or acts only automatically.

Nothnagel and Bastian favor the theory of Hitzig, but they differ in locating a centre for the "muscular sense" outside of the central lobules. The former declared to the Sixth Congress for Internal Medicine, held at Wiesbaden, that he had never known focal lesions of the motor zone to produce loss of muscular sense, but that such lesions were often accompanied by a loss of tactile sensibility. He places the sensory area in the parietal lobes, where he also locates, together with Seguin, the special centre for the muscular sense—a sense which Mills sees no reason for separating from that of general sensation. Nothnagel further states that the parietal lobes bear the

[1] Arch. für die gesammte Physiologie, Bd. 42.

same relation to the central and paracentral lobules that the convolution of Broca bears to the cortical hypoglossal motor centre. Injury to the parietal centres may produce ataxia without true paralysis, and injury to the central areas may produce paralysis without the loss of the muscular sense. This is somewhat of a return to the limitation views of Ferrier, and, in fact, both Nothnagel and Charcot separate the motor areas from the centres of cutaneous and muscular sensibility. For Charcot, however, the cortical motor centres are the seat of motor representations or conceptions, which must necessarily precede the accomplishment of any voluntary movement, while the muscular sense, or kinesthesic sensibility of Bastian, is subserved by the cortical centres of sensation.

According to Schiff, the so-called motor areas are entirely sensory, their activity is largely of the nature of a reflex, and the paralysis due to their injury is really the result of the loss of tactile sensibility. Munk does not believe that these centres determine movements directly, or in any reflex manner, but merely by the awakening of the mental images or representations of both general sensibility and motility. These ideational centres are not in immediate connection with the individual muscles, nor do they exert their influence directly for their individual actions. As Dr. Theodore W. Fisher[1] has tersely put it, "the will can only control and the mind is only conscious of movement in the mass." The fact that stimulation of certain areas of the cortex produces movement of groups of muscles and the co-ordinated movements of the segments of the limbs, shows that movements and not muscles are represented in the cortex. Many of the opponents of Ferrier's views have lost sight of this fact because this investigator insisted so strenuously upon the anatomical distinction and separation of the sensory and motor areas, and upon the sharp limitation of the latter to the central lobes. Munk's theory is popular in Germany, and makes the so-called motor areas entirely sensory. The activity of these centres results in "conceptions of movements," rather than the movements themselves. They are the psychical origin of the impulses which farther down the tract (possibly in the basal ganglia or anterior cornua of the cord) are transformed into the true motor stimuli that set the muscles into action. The cortical motor area is named by Munk, therefore, the "Sense-sphere" (Fuhlsphäre). Gowers' objection to this theory is that the "sense of innervation," an element of the threefold "conception of movement," is a sense of something which is not itself sensory, and which is commonly termed motor, and that destruction of this region causes loss of this "motor" function out of all proportion to any demonstrable sensory loss. The first of these objections seems weak to me; for it is a fact, as Stricker and others have demonstrated, that movements are preceded by psychical representations, which representations must obviously be of a sensory character. Franck inclines to the theory of a reflex action in the motor areas. He believes that the motor, like the sensory zones, are only the points of departure for voluntary motor impulses, while the true motor apparatus, or executive centres, are to be found in the cellular elements of the medulla and spinal cord. All of the cortical areas, according to this author, are merely centres of voluntary association. We know that the sensory and motor elements of the cortex are united by associating fibres, just as they must undoubtedly be lower down in the cord to complete the reflex arcs. The reflex phenomenon, both spinal and cerebral, necessarily presupposes such a union of the sensory and motor elements. This, it seems to me, can explain most plausibly the occasional association of the two sets of symptoms when the lesion happens to be limited to one or the other area. Such an assumption is not unwarrantable upon any anatomical or physiological basis, and it harmonizes most completely with the results of experimental and clinico-pathological observation—certainly more so than does the assumption that the motor and sensory areas coincide or consist of the same cellular elements.

Formerly all reflex functions were supposed to belong exclusively to the spinal cord, but to-day we consider the cerebral centres as much reflex as the spinal. Many of the Jacksonian epilepsies are undoubtedly of simple reflex origin. Mills[1] reported in 1880 a case, clearly Jacksonian in type, that had had seizures for eleven years, caused by a fibroma in the hand. When the tumor was removed the epileptic seizures eventually disappeared. "In the normal brain," Mills writes, "no reflex actions can be performed without exciting to action secondary volitional movements which no longer require the stimulating influence of a reflex action." The absence of gross cortical lesions in some forms of Jacksonian epilepsy, and Heidenhain's experiments in hypnotism, with other observations and facts, all prove conclusively the reflex function of the cortical centres of the brain.

Franck speaks of them as psycho-motor centres, because they control by their psychical influence the true motor apparatus. He says that "in examining the movements produced by the excitation of points under the control of the cerebral cortex, they may be regarded as analogous to reflex movements; but the essential difference between the movements so started and the ordinary reflexes consists in the point of departure of the original impulse. In one case it is cerebral, in the other cutaneous, but in every case it is peripheral in relation to the centre of motion (medullary centres)." Strictly speaking, then, the pyramidal tracts transmit *afferent*, and not *efferent*, impulses to the motor cells of the cord and medulla. Marique adopts somewhat this reflex theory for the motor centres; for he found that simple separation of the motor from the sensory areas, as a result of cutting the associating fibres, produced the same form of paralysis as when the cortical motor areas themselves were removed. He concludes, therefore, that the motor areas cannot act of themselves, but that, functionally, they are dependent upon impulses transmitted from the sensory areas of the parieto-occipital region. This question is far from being settled, however, since such varying results have been obtained in the experiments of Franck and Pitres, Marique, Vareth, Exner, and Paneth.

According to M. Soury, Lisso has collected, since 1882, some eighty eight cases in which disturbance of sensation accompanied cortical lesions of the motor area. Hence Tripier and Gilbert Ballet have named the cortical area the "sensitive-motor zone." Exner admits that the different areas for tactile sensibility of the various parts of the body are intermingled with the motor areas. In his study of aphasia[2] Dejerine says: "These disturbances of cutaneous sensibility accompany the beginning of the paralysis itself in the majority of cases, sometimes they even precede the latter. These phenomena are not rare in the course of a hemiplegia of cortical origin, and they deserve close study." The lesion in the case of Dejerine was limited exclusively to the motor cortex, leaving the sensory paths intact. Dupuy notes that Horsley reported to the Congress of Brighton, in 1886, that the removal of a part of the motor cortex in three patients, for epileptiform seizures symptomatic of cortical lesions, resulted in the partial or complete loss of sensibility. Seguin[3] and Weir reported the case of a man, aged thirty nine, who complained in the autumn of 1882 of severe head pain and convulsive attacks, limited to the right side of the neck and face. From 1885 these attacks occurred very frequently and were associated with a sensation of cold. The spasms involved the right arm and hand as well as the face. Finally paresis supervened in these parts, and was accompanied by aphasia and agraphia. The diagnosis was tumor in the facial centre of the left motor zone. Operation proved it to be a sarcoma, about an inch in thickness, nesting beneath the foot of the second frontal

[1] Cerebral Localization, American Journal of Insanity, October, 1889.

[1] Philadelphia Medical Times, December 18, 1880.
[2] Revue de Med., 1885. [3] Soc. de Biol., October 30, 1886.

and the anterior border of the ascending frontal convolutions. A report of the case in the *Journal of Mental and Nervous Disease*, of December, 1888, one year after the operation, states that there was unquestionably anæsthesia of the cheek, hand, and forearm to contact tests as well as with the æsthesiometer. There was also anæsthesia of the lower part of the face, lips, and inside of the cheek. From the study of the sensory tracts and of a series of American cases of cortical lesions, Starr [1] concluded that the motor and sensory areas coincided, though the former extended beyond the latter, and included the postero-parietal lobe as well as the Rolandic region. Four of the cases in Starr's list belonged to Mills, and in reviewing his notes the latter came to the conclusion that they at least did not support the inference drawn by Starr. From a careful review of one hundred and thirty-seven cases, Dana [2] decided that the sensory (tactile sensation) and motor areas were coextensive. In the discussion of Dana's paper Starr and Seguin argued with the author, but Mills favored the doctrine of Ferrier, namely, that the centre for tactile impressions was to be found in the gyrus fornicatus, and gyrus hippocampi. Stricker maintains that motion and sensation are so intimately related as to be almost identical. His views can be most clearly portrayed by an illustration. When one represents to himself, for instance, the movements of a cloud, the muscles of the eyes undergo the same sort of a sensation as though they were actually gazing at a moving cloud. By checking this muscular sensation within the eyes, the mental image of the cloud immediately ceases its movement. The cloud seems absolutely stationary.

Among the Italians Lussana and Lemoigne maintain that there are sensory and motor areas in the cerebral hemispheres, but that they do not act upon one another in the manner of a simple reflex. Tamburini, Luciani, and Seppilli have elaborated, since 1876, the theory that the "motor zone" consists, on the one hand, of the centres for cutaneous and muscular sensibility, and on the other, of the centres for motor ideations. This, as will be recognized, is a very elaborate, mixed, and comprehensive theory. It well illustrates, says M. Soury, the eclectic tendencies of the Italian school. As a general rule the Italians are as much opposed to the views of Hitzig and Nothnagel as they are to those of Schiff and Goltz. They incline somewhat to the theories of Ferrier and his English followers. In other words, they believe that the paralysis caused by injury of the cortical motor areas, pathological or experimental, is neither ataxic nor reflex. It is distinctly and entirely a paralysis in the truest sense of the word. Such at least is the opinion of Albertoni and Michieli, Lussana and Lemoigne, Tamburini, Luciani, Seppilli, Maragliano, Bianchi, Palmerini, Tonnini, and others. In the words of Maragliano, all motor phenomena should be regarded "as dependent upon true voluntary motor centres, which are capable, without the intermediation of any other motor centres, of starting into activity the muscular apparatus of the body." Equally clear in their statements are Luciani and Tamburini. These authors, unlike Ferrier, localize even the centres of voluntary motion in the basal ganglia, particularly in the corpora striata. Injury to these ganglia, as well as to the corresponding centres of the cortex, does not result in ataxia or the phenomena of inco-ordination; nor is any alteration of general sensation, including the sense of touch, to be detected in animals whose motor zones have been operated upon. The striate body, it will be remembered, is, according to Ferrier, the centre for movements which once were voluntary, but which afterward have become automatic. Thus a dog can still run and swim if the striate body remains intact, though the corresponding cortical areas have been removed. Luciani and Tamburini endow the basal ganglia with the same psychic functions as the cortical areas, and thus differ considerably from Ferrier. They speak of them as psycho-motor centres, probably meaning thereby that the basal ganglia, as well as the cortical motor centres, are in direct connection with the sensory centres. "The basal ganglia," they say, "and especially the corpora striata, possess the same physiological value as the centres of voluntary motion, or, in other words, these centres can be put into action directly by psycho-sensitive sensorial processes." When the authors promulgated these ideas, it was supposed that the function of the striate bodies was motor; now, however, it is known that the hemiplegias due to hemorrhage in this region are the result of the injury done to the internal capsule. In fact the striate bodies have been completely transformed into cysts, and yet there was no paralysis so long as the internal capsule continued intact. Hence these earlier views of Luciani and Tamburini are now quite untenable; nevertheless it must be admitted that the recent study of the striate bodies (caudate nuclei) by Baginsky and Lehmann seems to reveal some truth in the earlier views of these Italian authors.

The so-called paralysis, resulting from a destructive lesion of the excitable zone of the cerebral cortex is believed by some of the Italian writers to be due entirely to the loss of sensation. Silvio Venturi,[1] of Padua, adopted this ataxic theory in 1878. It was Schiff, the distinguished predecessor of Luciani in the chair of physiology at Florence, who became the chief exponent of this sensory explanation of the paralysis. In 1871, the year after the experiments of Fritsch and Hitzig, the editor of *l'Imparziale Medico*, inspired by Schiff, wrote that all the immediate effects of injury to the so-called motor centres of Hitzig were really the result of a disturbance of sensibility and were limited entirely to that sphere. In several Florentine publications, issued in 1873 and 1876, Schiff recalls these facts. According to this physiologist, a dog with a cerebral lesion is not affected with any loss of energy in the muscles of the opposite half of the body, but merely with an absence of the feeling of surety and power of adjustment in its various movements because of the loss of tactile sensibility. The general movements of running and leaping are all well performed, but there are marked evidences of an uncertainty in regard to the position of the limbs. This anæsthesia is entirely cutaneous, according to Schiff, while the sensibility to pain and pressure remains undisturbed. Alternations of the sense of pressure and temperature are caused by the increased depth of the cerebral mutilations. While these views, together with the experiments of Schiff, are not accepted by the majority of physiologists, they have very greatly modified the original theories of many of them in regard to the motor character of the so-called motor areas. Hitzig himself, who was so vigorous a supporter of the purely motor theory, has altered his conceptions to such an extent as to refer to these motor phenomena under the name of disorders of the muscular conscience. Schiff's theory is that of a pure reflex. An impulse from the periphery, for instance, is sent inward to the brain, and there, within some hitherto undiscovered subcortical centres, is transmuted into an efferent impulse, which is sent out again to the muscular apparatus. This cerebral reflex, he insists, is similar to the spinal reflex, and the phenomena due to its disturbance are similar to the reflex phenomena due to injury of the posterior columns of the cord. It should be noted that Schiff locates the reflex centres not in the cortex itself, but somewhere beneath the cortex. There have been many objections and objectors to these views of Schiff, and his followers form quite a small minority. But it must be admitted that, like his opponent Hitzig, he has done valuable service to the science of cerebral localization, for if Hitzig discovered the results of injury to the motor areas of the cortex, Schiff revealed those due to injury of the centres for tactile sensation. To judge from the doctrines of Munk, Luciani, and Seppilli, the

[1] Journal of Nervous and Mental Disease, New York, July, 1884.
[2] Ibid., October, 1885.

[1] Arch. Ital. per le mal. nerv. 1878.

future will have to acknowledge Schiff, as well as Hitzig, as one of its forerunners. When Schiff asserts that "one thing is positive, there are no cortical centres,"[1] we are somehow forcibly reminded of Goltz. Though Schiff can enumerate many objectors, chiefly among the followers of Ferrier, such as Lussana, Tamburini, Bechterew, and Horsley, his teachings, like those of Goltz, have acted as a wholesome check upon the too rapid assumption that all movements of the body originate from certain limited areas of the cerebral cortex. They have induced experimenters to study somewhat more minutely the character of all muscular movements, the relation of the centres for these movements to the centres for sensation, and the influence, if there be any, of the higher mental faculties, the purely psychic functions of the brain. The extremely difficult and complicated nature of the problems involved taxes the keenest powers of the psychologist as well as of the physiologist.

Tamburini has attempted a reconciliation of the two opposing views just noted. He admits it is probable that the points of the cortex where the inpouring sensory impulses are transformed into outgoing motor impulses correspond identically with the cortical areas upon which so much study has been expended. In his own words, "each of these centres may be at the same time the focus for the reception and perception of the sensory excitations sent inward from a given part of the body, and the point of departure for the voluntary centrifugal impulse going to the muscles of the same part." This, he believes, explains the absence of sensibility in the direct production of localized movements; for in the one instance the electric current takes the place of the nervous current or impulse, and in the other the removal of the cortical centres must necessarily abolish the perception of the peripheral impressions. In conjunction with Luciani, Tamburini has extended this same theory, in regard to the excito-motor zone of the cortex, to the centres for sight and hearing. The movements of the ear and eyeball, initiated by a sensory impression at the periphery, are not of the nature of a pure reflex, as Ferrier believes, but simply the result of the intermingling of the corresponding sensory and motor cells of the cortex. In other words, corresponding sensory and motor cells lie in close juxtaposition within the various cortical areas. These views of Tamburini seem to be supported by an anatomical as well as physiological basis; for, as I have already pointed out, the region of the hippocampus major, which Ferrier and his followers assert is sensory in function, contains a row of large pyramidal cells between the medullary centre and the so-called stratum radiatum; and these cells are identical, so far as their microscopical appearances are concerned, with the supposed motor cells of the central convolutions and of the anterior horns of the cord.

In 1880 Luciani, who, like Seppilli, found that the effects of a circumscribed lesion within the motor areas of the cortex were not only paralysis or paresis, but also an alteration of the muscular and cutaneous sensibility more or less pronounced, wrote that "the motor centres and the sensory centres, which together perform a very complex function, are intermingled, or lie in the closest proximity (*in gran vicinanza*) within the cerebral cortex." He verified the phenomena described by Munk, but he did not look upon the paralysis as psychical in character; that is, as the result of the loss of mere sensation of mental images or of psychic representations. It was purely organic and depended directly upon the injury to the motor cells, just as the disturbed sensibility depended upon the injury to the neighboring sensory elements. The motor centres, therefore, like the centres for sight and hearing, were of a complex nature, and in reality sensori-motor. Luciani says, "The motor centres are not localized within the cortical area called up to the present time 'the motor zone,' a name which we must hereafter abandon, since this zone is not exclusively motor. All the different regions of the cortex are more or less strewn with special motor centres. In order to be positive of having destroyed all the motor centres, one must remove the entire cerebral cortex." This is a remarkable statement of a singularly comprehensive theory, and leads us back once more to the vigorous discussions of Goltz.

Danillo has demonstrated that when the occipital lobe —which is supposed to be entirely sensory in function—is stimulated, the movements of the eyes are not simply reflex, as Ferrier taught, because they are still observed when, after the ablation of the entire cortex of the occipital lobe, the underlying white substance is electrically excited. In this white substance, therefore, there must be motor fibres springing directly from the cortex of the occipital lobe, unless we imagine that these same fibres go to the central lobules, and through them, rather than directly, transmit the motor impulse to the muscles of the eye. Even such a conception, however, would represent the process within the occipital cortex as reflective, but the outgoing impulse in such a case would be transmitted into an ordinary motor one before it finally reached the eye muscles. This difficulty might have been solved by removing, as Goltz has done, the entire cerebral cortex except that of the occipital lobe, then exciting the latter, and noting whether there were any movements of the eyes. I do not know whether such an experiment has been performed, but it is one which, if possible, is greatly to be desired. In fact, each of the sensory areas should be thus isolated, excited, and the effects closely studied in regard to the production of any motor phenomena. Since the distinguished physiologist of Strasburg has succeeded in removing vast amounts of brain-substance without destroying the lives of the dogs, it would seem that such experiments as suggested would be quite feasible. Bechterew has accomplished this to a certain extent, and finds that when the so-called motor areas of the central lobules are separated from the occipital centres, stimulation of the latter still gives the same muscular response. He argues, furthermore, that the movements of these muscles cannot possibly be of the nature of a simple reflex, because they are always uniform and localized within the same group. Stimulation of the occipital cortex excites motor points, therefore, that do not belong to the so-called motor zone, whose fibres pass only through the pyramidal fasciculi of the cord. These mixed centres being situated thus outside of the cortical areas to which the pyramidal fasciculi run, require for their excitation a much stronger and longer current; their destruction does not involve manifest disturbances of motion; and the movements which they give rise to are not very clearly differentiated from those caused by excitation of the true motor zone. Bechterew argues, therefore, that the sensory areas do contain motor centres, or at least motor elements, and he accounts for the fact of their stimulation requiring a stronger current and one longer in duration, on the ground that they do not connect with their corresponding muscles through the intermediation of the anterior roots of the spinal cord, but through certain masses of gray matter situate l deeply within the cerebral hemispheres, probably the optic thalami. According to Bechterew, then, there are two sorts of motor centres within the cerebral cortex. One variety is easily excitable and found in the central convolutions; the other is not so easily excited, and is scattered in among the sensory centres. This author bases his views chiefly upon his experiments on new-born animals, in which the movements of the ear and the conjugate movements of the eyes, for instance, can only be produced by direct stimulation of the corresponding areas of the cortex, one week and one month, respectively, after the movements of the limbs have been elicited by excitation of the central convolutions.

We have thus seen that the sensory areas of the cortex do contain motor elements, and that in all probability they exercise some special influence upon the associated muscular apparatus. From our rapid review of the modern theories among the English and German physiolo-

[1] Pflüger's Arch. f. Physiol., xxx., 253.

gists, we note that there is a growing tendency to believe that the motor centres of the central convolutions have sensory elements intermingled with them.

Luys [1] remarks that certain convolutions are distended and hypertrophied when certain cerebral symptoms have been present. In cases of delirium with delusions and hallucinations, he found a pronounced gibbosity of the paracentral lobule, to which is usually assigned a strictly motor function. It is unfortunate that no mention is made as to whether the delusions and hallucinations partook of the motor more than of the sensory type, whether they were mental representations of abnormal kinesis or æsthesis. They seem to show, at all events, that the cortical areas, both motor and sensory, are ideational and psychic, psycho-motor and psycho sensory, rather than simply organic. Mickle [2] has shown that hallucinations are due mostly to lesions of the sensory centres of the brain. Thus lesions of the angular gyrus produce visual, and of the temporal gyrus auditory, hallucinations, but not to the full extent that one would have been justified in anticipating. This shows, therefore, that sight and hearing are not dependent upon these centres solely.

The centres of general sensation, by which we mean those for touch, pain, and temperature, are usually located just back of the motor centres in the parietal lobe, between the calloso-marginal, parieto-occipital, and retro-central fissures. These are less clearly differentiated than the corresponding motor centres. It is possible that our ignorance in this respect is due to the general unreliability of sensory as compared with motor symptoms, and the difficulty which we experience in deciding always the exact nature of a certain symptom, which may be in fact purely sensory, but which by reason of the pain, restless discomfort, and reflex phenomena, unavoidably gives rise to abnormal movements and other motor appearances. The cells of the sensory areas are pre-eminently receptive, and neither physiological experiment nor clinico pathological observation has yet proved that they are in any way directly emissive. There can be little doubt but that they are connected with the motor cells of the cortex, and transmit special impulses to the latter. These two sets of cells, thus intimately united, form the summit or bend, as it were, of the arch about which the sensori-motor impulses travel, and are therefore in all likelihood the true physical basis of mind. The gross character of the general sensibility and of the movements of the body, as compared with that of the organs of special sense, necessitates the corresponding sensori-motor ideational centres of the cortex being so much more developed than the centres for the special senses. In connection with the sight and hearing, the proof is pretty conclusive that sensory and motor cells lie in close juxtaposition, and are most intimately conected by associating fibres. We infer that the same ideational centres cap the arches about which play the afferent and efferent impulses from the eye and ear. Hence I take it that the cerebral cortex is, after all, only a grand reflex centre. It is far more delicately organized and specialized, however, than the reflex centres of the cord, but in all other respects it is quite comparable to the latter.

The morphological and embryological development of the brain throws a flood of light upon the relations of its motor and sensory elements with each other. Among the invertebrates there is no brain or spinal cord such as we find among the higher orders of animals; nevertheless the spinal cord of the latter is clearly foreshadowed in the single series of sensori-motor ganglia, with their projecting nerves, found in the respective segments of the invertebrate. In the articulata and insecta we know that each segment is furnished with a little brain of its own, which is nothing more nor less than the summit of the reflex arc for that particular segment; and we furthermore know that the little brain of the most forward segment of the creature is but a ganglionic development of the cord, comparable to the various ganglia of the other segments. This is illustrated beautifully in the anatomy of the worms and insects. In some of the higher representatives of these orders the ganglia of the most anterior part of the body become massed together, undergo a somewhat fuller development to subserve the purposes of certain special sense-organs, and so in a measure assume the characteristics of the brain of the vertebrates. Note as illustrative of this the exquisite arrangement of the nervous system of the white ant (Termes), the fly (Musca), and the scorpion spider (Thelyphonus caudatus). In all of these creatures the various segmental ganglia are connected with each other like the cells making up the circuit of an electric battery; and some of them are so far advanced in development as to simulate, without representing, the brain and spinal cord of the higher mammals. As we proceed up the scale of evolutionary advancement we behold the nervous system becoming more and more complicated and specialized, assuming more and more the nature of the primate brain and spinal cord. In the vertebrates, and even their highest representatives, man and the apes, the primitive invertebrate appearance of the cerebro-spinal axis is not wholly lost. As Owen says, a vertebrate is but a clothed sum of segments, and therefore nothing more nor less than a higher invertebrate. In the lowest vertebrate, the *amphioxus lanceolatus*, there is only a spinal cord without a brain, and in all its habits this creature closely resembles the invertebrates. The peculiar character of the vertebrate skull, which is now admitted to be composed of metamorphosed vertebræ, the embryological development of the brain and spinal cord from the same germ-layer, and the similarity of the brain and cord up to a certain point, are all extremely indicative of the primitive characteristics of the encephalon of man. It seems to me that, if there be any truth whatever in the principle of evolution, it is not irrational to look upon the brain of the vertebrate as a highly developed portion of the spinal marrow, or of the ganglia of the spinal cord lying most frontad. If such be the case, we would expect some similarity between the arrangement of the sensori-motor elements of the brain and those of the vertebral segments of the spinal cord. The motor cells would not be identical with, but rather lie in close proximity and intimate relationship with their corresponding sensory cells. The extreme simplicity of this arrangement in the cord is, of course, quite obliterated by the overcrowding of so vast a number of nervous elements in so confined a space as the cranium. In this, however, we see somewhat a confirmation of the doctrine that the brain is a composite rather than a simple organ. The rolling about of the encephalic ganglia during their embryological and evolutionary development, in order to accommodate themselves to the constrained limits of the interior of the skull, results in a disappearance of that relative and simple arrangement of the sensory and motor elements which we see in the vertebral segments of the spinal cord. Nevertheless, the actual arrangement is even still such that we can faintly distinguish the resemblance to the spinal arrangement; we can recognize the fact that the ganglia and cortex of the brain are like the summit of the sensori-motor reflex arc as we find it more clearly presented in the cornual sensori-motor arcs of the spinal segments. In the brain it is seen, for instance, in the relative arrangement and mutual development of the cortical motor and sensory areas. General sensation is the least specialized of the sensory functions of man, and being co-extensive with the entire surface of the body proves man's connection with the lower animals. The corresponding development, the similarity in extent, and the relative antero-posterior location of the cortical sensory and motor areas, reveal their connection with similarly related parts of the body, and their similarity with the sensori-motor arcs of the spinal cord. Their excessive development in size and function gives them a preponderance over the corresponding segments of the cord, and in their function, especially, makes them appear as

[1] Le Progrès Médical, 1889.
[2] Jour. Ment. Science, October, 1881, January and April, 1882.

though they were voluntary, while the latter were involuntary. But voluntary and involuntary are relative terms, expressing different degrees of the same form of nervous activity. The psychic functions of the cerebral cortex are involuntary quite as much, if not in so glaring a manner, as the involuntary functions of the various segments of the cord. They are both alike a form of reflex action, but instead of the cerebral reflexes being direct and unconscious as they are in the cord, the more sensitively and highly organized character of the cortex causes them to assume the character of consciousness and self-will, while the connection of the cortex with the segments of the cord, as these in turn are again connected with one another, causes the cortical reflexes to be transmitted and perceived through the medium of the spinal centres rather than directly from the periphery of the body. In regard to the special senses of sight and hearing, the reflex sensori-motor arc does not pass through the cord or its ganglia, but is limited solely to the encephalic ganglia, while their sensory elements are always posterior to, and more or less in close proximity with, the motor elements, just as they are in the spinal segments.

The bi-lateral character of the spinal cord functions is duplicated in those of the encephalon.

At the session of the Société de Biologie of Paris, May 25, 1889, M. Dupuy reported a case showing the identity of the two hemispheres of the brain in regard to their functions. The patient possessed the power of moving the two eyes in different directions at the same time. Even the perceptive centres were distinct, despite the opinion of Horsley to the contrary, for the young woman saw objects with one eye, and when she tried to use both eyes together to view the same object she was overcome with dizziness. Magnan[1] has had four cases of this sort, one of which he reported in full. The patient heard one class of statements in one ear and another in the opposite ear. Agreeable ideas only were received on one side of the head, disagreeable ones on the other. Brown-Séquard long ago insisted upon, and physiologists are now beginning to recognize, the fact that the two hemispheres have identical functions. Hence I conclude that man's mental activity is largely automatic and reflective; that the cortical centres for ideation are constituted, related, and localized, with respect to one another, much like the reflex centres of the spinal cord, but that the finer development of the former gives them a finer degree of activity; that the sensory and motor elements of the cortex are not identically the same, but are separate, closely intermingled, and intimately connected with one another; and that an explanation is thus afforded of the simultaneous appearance of the two sets of symptoms, motor and sensory, in corresponding parts, when an irritative or destructive lesion is limited entirely to one or the other of the associated cortical areas.

If this progressive differentiation of function, based upon the principle of reflex action, continues within the encephalon as it has up to the present time in the evolutionary development of the nervous system of animals, it may ultimately happen that the mind will be capable of thinking upon two or more subjects at one and the same moment. Its capabilities will thereby be immensely enhanced, and the old dictum of the psychologists, that the association of two or more ideas is always consecutive, never coincident, will be overthrown. In his paper upon the "Molecular Dynamics of the Encephalon," published in the *American Journal of Insanity* for October, 1889, Dr. Williams has hinted at this future possibility. "Who knows," he asks, "but that the more fully evolved mind of the future shall learn, after the present mind has come to look with stunned discouragement upon the vast field of knowledge presented to its view by an advanced civilization, gradually to so adjust its fibres and its vessels by isolating them into separate fields momentarily (since the isolation is the acme aimed at by the higher mind in its concentrated workings to-day), that consciousness may, in fact, come to be not a single energy but a double, triple, quadruple, or multiple energy? Imagine, for example, the school-boy of the thirtieth century studying his mathematics visually with concentration, while orally listening to a lecture on a different topic. In all seriousness, there seem to be some reasons for believing that such a seemingly paradoxical mentality may be evolved." The tendency of mental development is certainly in this direction. It is already so striking a characteristic of the human mind as to place man infinitely above the lower animals. The separation of the various representative areas of the cortex, so that even now an animal can feel a prick in the foot, move his paw, and listen attentively to some unwonted sound all at the same moment, would seem to give promise of such a desirable future possibility.

A mere glance at the localization of the various centres of the cerebro-spinal apparatus, when compared with their relative functions, favors the view of the similarity of the brain and cord in regard to their primitive structure, and of the more ancient and higher development, both anatomically and physiologically, of the forward part of this nervous apparatus. When closely studied, it appears that inhibition is the highest function of all nervous matter. To inhibit an action presupposes a finer degree of development on the part of a nervous centre than merely to receive and transmit a reflex impulse. Inhibition is the real nature of mind, and is of so startling a character as to give the impression of absolute independence resulting in free will. The inhibitory function of the mind is admitted by all physiologists and psychologists, while the former assert that, were it not for this magnificent function of the highest of all the cerebral centres, our bodies would be kept in a constant state of convulsion through the manifold impulses which our nervous systems receive and reflect outward again to the muscles. Mills speaks of the higher psychical centres in the fore-brain as constituting the "inhibitory lobe." When we remember that all mentalization is based upon sensory and motor phenomena, and that the cortical areas for the psychical representation of these phenomena are quite definitely outlined, we are not surprised that there should be so much mystery surrounding the functions of the unknown areas of the brain. We note that injuries of the pre-frontal lobes result always in mental deterioration with abnormal psychical phenomena, while it is generally admitted by the best physiologists that one function of this *terra incognita* of the cerebral cortex is at least inhibition. Putting all facts and inferences together, then, we may safely conclude that the power of inhibition is the last of the acquired functions and the special characteristic of the most highly organized nervous matter; that this power resides in the gray matter of the pre-frontal lobes to a very high degree; and that therefore they are pre-eminently the psychical centres irrespective of the mind, being the result of the combined activity of all the sensori-motor elements of the cortex. And we furthermore infer that this anterior, highly specialized portion of the brain, differs from the rest of the nervous apparatus in structure and function in degree rather than kind. I take it, therefore, that all inhibitory centres are higher in development than the centres which they inhibit.

In the organic evolutionary progress of the animal the centres of the medulla that preside over the vital processes may be the oldest in time. They are first because they are necessary for life itself, but in the physical development of the animal there are centres which precede these in importance, and if, as the biologists tell us, the more highly organized matter is the most ancient, these important physical centres may, after all, be the oldest in time, while the centres of the medulla may be simply later differentiations of nervous matter set apart for the special regulation of the vital processes. It is probable, therefore, that the highly specialized, inhibitory, psychical centres of the fore-brain are the most primitive portions

[1] Journal de Méd. de Bordeaux, September 30, 1883.

of the nervous apparatus, so far as the evolutionary development of nervous matter goes; though from the embryological stand-point the cord is the primitive factor. In its influence upon the next lower centres, namely, the so-called sensory and motor areas of the brain, the fore-brain is comparable to the latter in their inhibitory influence upon the centres of the medulla and spinal cord. The inhibitory function is thus graduated from the highest psychical centres of the fore-brain down to the lowest organic centres of the cord, where it is practically so overpowered by the inhibitory influence of the higher centres that it appears entirely absent, permitting the cord to act only as a gross and unobstructed reflex centre. In its evolution, therefore, the whole cerebro-spinal axis seems to be but a series of connected sensori-motor ganglia or reflex couplets differing in different parts more in degree than in kind.

Even in the relative positions of the various subcentres of the motor area of the cortex, there can be recognized a certain correspondence with the associated parts of the body, if it be remembered that the head of man is bent sharply forward to accommodate it to the erect position of the body. In like manner with the corresponding parts of the body, the centres of the cortex follow one another from front to back in the order of the head, arms, trunk, and legs. This is illustrated otherwise in the fact, as pointed out by Horsley,[1] that the variation in the representation of motor functions is more marked as the motor area is traversed from above downward than from before backward. In other words, by carrying the faradic stimulus backward over the cortical motor area, the parts of the body affected follow more naturally in the regular order than if the same stimulus were carried over the same cortical area from above downward. The relative smallness of the representative area for the trunk muscles, as compared with that for the extremities, has been well accounted for by Mills, on the ground that the movements of the trunk are simply subordinate to the purposive movements of the limbs, and hence require only a comparatively small part of the cortex for their primary representation.

In summing up, then, I would offer the following propositions:

1. The motor and sensory areas of the cortex are not sharply distinguishable from one another, as was at first supposed by Ferrier and his followers.

2. Nor are they, as separate areas, of such character and unimportance as to render the action of the brain practically that of a uniform single organ, for which Goltz and his school contended.

3. There are separate motor and sensory centres within the cortex, but they are closely intermingled and most intimately connected with one another.

4. Both the motor and sensory areas have foci of special intensity; the former in the central, the latter in the postero-parietal, lobules.

5. While there may be a general inter-communication between all the sensory and motor elements of the cortex, there is the most intimate connection between the related sensory and motor cells that preside over corresponding parts of the body.

6. The primary function of these cortical sensori-motor groups of cells as couplets is reflective, like that of the sensori-motor reflex arcs of the various spinal-cord segments. This is shown by the morphological and embryological development of the cerebro-spinal axis; and it explains most satisfactorily the majority of the sensori-motor phenomena of physiological experiment and clinico-pathological observation.

7. Mentalization and thought itself are dependent upon sensori-motor phenomena, so that there is a strong probability that mind itself is the product of the activity of the entire cortex.

8. The power of inhibition is apparently the latest and highest differentiation of the functions of nervous matter, though it is itself a latent function of all nervous substance, varying in degree merely with the stage of the latter's development.

9. Inhibition is the special function of the fore-brain, and therefore endows this part of the nervous system with a commanding influence over the rest of the nervous apparatus. The fore-brain is therefore pre-eminently the psychic centre, though when exhaustively analyzed its inhibitory and reflex functions differ from the inhibitory and reflex functions of the ganglia lower down in the cerebro-spinal axis, in degree rather than in kind.

10. The sensori-motor functions of the cerebral cortex are psychical in character, and influence the external parts of the body only through the mediation of the cord and special ganglia, just as the highest of all the psychic centres, the fore-brain, influences the body through all the sensori-motor centres of the cortex, special ganglia, and spinal cord.

11. In fine, inhibition and reflex action being the special property of all nervous matter, they are found in varying gradation as the functions of the most highly organized matter of the fore-brain, which therefore seems to be the special seat of mentalization, down to the most primitive ganglia of the spinal cord, which retain only the lowest degree of reflex irritability.

TWO CASES OF METASTATIC CHOROIDITIS.

By W. F. MITTENDORF, M.D.,

NEW YORK.

Metastasis, as its name implies, means the transmission of a local disease from one part of the body to another. Among affections of this kind involving the eyes we have certain forms of rheumatism, especially of the gonorrhœal variety, tuberculous diseases, and cancerous growths, and lastly pyæmia; the latter is especially liable to lead to the formation of septic emboli in the uveal tract.

Cancer is looked upon by many as a local disease, and it will often give rise to metastatic affection. Sarcomatous tumors, for instance, are apt to involve the eye after having existed in other parts of the body, and even after the removal of the affected parts; sometimes shortly after the operation, at other times it may be a year or more before the sarcomatous growth is observed. In one case in which I diagnosed a sarcoma of the choroid in an old lady, it was found that the first symptoms of a disturbance of vision had been observed a few weeks after the removal of one breast for cancer—the patient being in bed at the time on account of the operation. The sight of the affected eye had not been impaired in the least before this, the patient having had glasses adjusted and her eyes examined shortly before the operation was undertaken. Two weeks later I examined the patient and discovered, as I said before, positive evidence of the existence of a small nodule in the choroid of the left eye, which in course of time developed into a well-marked sarcomatous growth. These tumors of the choroid are, of course, not always metastatic; they are generally primary ones, and are often followed by similar growths in other parts of the body, which sooner or later bring about the death of the patient. Of an even more striking and alarming nature are, however, those metastatic affections of the choroid which manifest themselves by a more or less extensive inflammation of this part of the eye, because they are always accompanied by a sudden and very dangerous blindness of the affected eye. Such an inflammation is generally confined to the eyeball; but it will frequently extend to the surrounding parts, such as the capsule of Tenon; and even the orbital tissue itself is liable to become involved, causing intense suffering to the patient, and not infrequently results in the death of the sufferer.

Metastatic choroiditis is of bacterial origin, and is usually due to some septic material, which has been absorbed in other parts of the body and is then deposited in the most vascular tissues of the eye, the uveal tract, and im-

plicates either the choroid, the ciliary body, and the iris, or all of them. The absorption of this dangerous material does not infrequently take place at a very remote part of the body, from the subinvoluted uterus after confinements, for instance, or even from septic processes going on in the lower extremities; though, strange to say, it is very rare that in purulent diseases of the ear, which is in so close proximity, the eye becomes affected; it is here the brain which is most liable to become involved, and, as is well known, the formation of metastatic abscesses of the brain is not very rare in severe purulent diseases of the middle ear. The channels by which the septic material is transmitted cannot be definitely given; whether the blood-current or the lymph fluid are the carriers has not yet been definitely settled. The most recent investigations seem, however, to point to the blood-vessels as the probable source, and in support of this view we have especially the report of a case of metastatic choroiditis occurring in pyæmia after a complicated fracture, by L. Weiss, made at the Ophthalmological Congress in Heidelberg, in 1875, in which the microscopic investigation revealed an actual thrombosis of the choroidal vessels of the affected eyes.

On the other hand, those cases complicating severe meningeal troubles, or which occur at times almost epidemically after severe forms of typhoid fever, where the source of the septic material is without doubt from the ulcerated intestinal glands; or after severe cases of small-pox, or even in measles, and especially in cerebro-spinal meningitis, the probability is that by the lymph-spaces and channels the bacteria are transmitted to the choroid.

The former view has its defenders in such authorities as Knapp, Virchow, Weber, and others, and the blood-vessels in the neighborhood of the infection have always been found to be full of septic microbes. The latter seems more probable in a certain number of affections on account of the connection of the lymphatics of the choroid with the arachnoid spaces of the brain.

Metastatic diseases of the eye, especially if we omit those rheumatic inflammations which have sometimes been looked upon as of a metastatic nature, are usually due to some severe disease or a traumatism of which septicæmia is the result. Of these affections the puerperal state furnishes the most frequent, and likewise the saddest, cases of this kind, one of which was reported by Dr. T. S. Parley some time ago. Next to this class come suppurating diseases of the joints; in fact, in all those purulent processes occurring in such parts of the body where, on account of the rigidity of the tissues, there is apt to be a patency of the veins, the absorption is more liable to take place. This affection has likewise been observed in severe constitutional diseases associated with, or followed by, suppuration, such as the exanthematous fevers, cerebro-spinal meningitis, and others; and, as before mentioned, there have been epidemics of these diseases, marked by the occurrence of a large number of metastatic affections of the choroid.

A choroiditis of this latter variety does not always manifest itself in a very severe form; there are cases where the deposit of the septic material does not appear to lead to a complete breaking down of the affected parts, and where a partial recovery is noticed; in these cases, which are not so rare, the nature of the inflammation set up by the septic embolus is perhaps more of a plastic than of a purulent nature. They are observed in children after attacks of meningitis however. Even these milder cases lead, as a rule, to great impairment of vision, and even to atrophy of the eye and complete blindness.

I have seen cases of this kind during several of the epidemics of cerebro-spinal meningitis which we had here several years ago, in which the first symptom of any trouble of the eye was the appearance of pus in the anterior chamber and discoloration of the iris; the patients being too ill or too small to complain about the blindness which we know exists with, and is one of the earliest symptoms of, this disease of the eye. In these cases it is hardly possible to think of a direct extension of the meningeal inflammation along the optic nerves to the choroid; it appears more plausible that the peculiar microbes found their way through the lymph-spaces and the sub vaginal space of Schwalbe, and from here travelled to the choroid.

We do not often have occasion to see cases of this kind at our ophthalmic clinics and dispensaries, because the original diseases are usually of such great severity that the patients are kept in general hospitals, or do not recover at all. The few cases which I have seen were very sad ones; as a rule, both eyes become affected, and when not phthisis bulbi and hopeless blindness existed there was so much plastic material present that the cases resembled those of a glioma of retina; there were white glistening masses of exudation projecting into the vitreous humor and reaching almost up the lens, and even surrounding the latter on all sides in some instances. The history and the absence or scarcity of superficial retinal vessels on the surface of the growth, and existence of posterior synechiæ of the iris, made the diagnosis between them and a retinal glioma as a rule quite easy, although the similarity of the appearance of these affections is so striking that our English confrères have called it pseudo-glioma. The prognosis of these cases is naturally very bad. The difficulty of diagnosis referred to exists of course only after all inflammatory symptoms have subsided and the history of the original disease is unknown. During the acute state there is no difficulty to recognize the disease, even in very small children.

The true metastatic suppurative choroiditis, as we observe it after suppurative inflammation of the joints, after purulent endocarditis, during the puerperal state, or after empyema and other septic diseases, gives us, however, an entirely different clinical picture, and so severe are the accompanying symptoms that early English writers have justly spoken of it as an abscess of the eye rather than as a choroiditis. If the disease is so marked on its onset, it will soon implicate the neighboring tissues, and has been named a panophthalmitis, a disease which is so much dreaded after severe ulcerations or injuries of, or after operations upon, the eyeball. The metastatic choroiditis is usually of this variety; it is ushered in and accompanied by chills and marked febrile disturbances; some sharp shooting pains are likewise felt in the beginning of the disease, and more or less complete blindness follows quickly; the iris becomes discolored, pus is liable to show itself in the anterior chamber, and the capsule of Tenon becomes soon implicated. There is marked ciliary injection, although this is soon masked by the intense hyperæmia of the conjunctiva; the lids become œdematous and marked chemosis raises the conjunctiva of the eyeball in the form of semi-transparent bags which protrude through the palpebral opening. The proptosis of the eyeball becomes now quite striking, the swelling extends to the surrounding parts of the face, and the pain, which soon becomes of a hemicranial nature, is so intense that the patients are in a very deplorable condition; they cannot sleep and are more or less delirious. The pupillary reflex is lost, and the fundus is not visible with the ophthalmoscope. The eyeball itself is very painful to the touch and shows marked increase of tension. On account of the purulent infiltration of the vitreous, which takes place almost immediately after the onset of the disease, the pupil appears yellowish-white and is more or less dilated in the majority of cases, on account of the high intra-ocular tension, which has a paralyzing effect on the sphincter of the iris, and neither light nor mydriatics will affect it. The cornea is anæsthetic and, if not actually infiltrated and on that account opaque, appears steamy and without its usual lustre. Were it not for the absence of a purulent discharge of the conjunctiva, the superficial appearance would not be very unlike that of some severe purulent forms of conjunctivitis, of the gonorrhœal variety, for instance.

The iris and the ciliary body are early implicated, and this gives rise to the severe hemicranial pains, as well as to

the great tenderness of the eyeball to the touch. At times there is some plastic exudation which gives rise to adhesions of the iris to the lens, but as a rule the product of the inflammation is purely of a purulent nature. On account of the presence of pus or other inflammatory products, the color of the iris is changed and contrasts strangely with that of the other eye.

Sooner or later the pus will force its way through the sclera in the neighborhood of the cornea, most frequently in the region between two recti muscles; the acute symptoms subside and the eyeball will get soft and become phthisical and recede into the orbit. In milder cases there may not even be a perforation of the eyeball, but as the inflammatory symptoms subside the eye becomes soft and the exudation is gradually more or less completely absorbed, or undergoes degenerative changes and contracts. However, vision is rarely preserved, even in the very mild attacks.

Cases of metastatic purulent choroiditis are not often met with in ophthalmic hospitals, as the patients are as a rule too sick from the original disease to seek the advice of a specialist, and are therefore treated at home or in general hospitals. In looking over the history of the subject, I find only four or five cases of this kind reported during the last fifteen years. One of the most interesting ones is that reported by the chairman of our meeting, Dr. Thomas R. Pooley, to the State Medical Society at Albany in the year 1875. In this case the disease developed fourteen days after a very severe confinement, and although perforation did not take place, all parts of the eye were so thoroughly involved in the inflammation that the patient would have been blind, had she lived.

Another case was reported in "Schmidt's Jahrbücher," 1881, where a physician infected himself by using an impure hypodermic syringe, which was followed by septicæmia and death. During the progress of the disease a metastatic choroiditis developed in the right eye, and resulted in perforation of the eyeball.

The next case was reported likewise in "Schmidt's Jahrbücher," and is that of a man who had an abscess of the neck, which was followed by suppurative choroiditis and loss of the eye.

Dr. Sutphen reported to the American Ophthalmological Society a case of double-sided metastatic choroiditis of both eyes after meningitis, which, however, appears to have been more of a plastic than of a purulent nature.

On account of the scarcity of the disease, and the limited number of cases reported during the last ten or fifteen years, I shall proceed to give the history of two cases of metastatic choroiditis which I had under observation a short time ago.

Case I.—Mr. N-—, laborer, aged forty, was admitted to Bellevue Hospital on account of a swollen and painful knee-joint, which was supposed to be rheumatic, as no history of an injury could be elicited. The man had a moderate amount of fever, and was in a rather weakened condition. The affection of the knee-joint did not improve and the temperature remained high. The knee was opened and the presence of pus demonstrated a purulent affection of the joint. During one night, a few weeks after the operation, the patient complained about flashes of light and great pain in his left eye. The next morning he found that he could not see well. There were hardly any signs of inflammation visible, but the pain kept on increasing during the day, and the next morning the eyeball appeared red and irritable, the upper eyelid was somewhat swollen, and there was some slight prominence of the eye. Ice compresses were now applied, but the pain and other inflammatory symptoms increased steadily, and the patient could not even see the window with the affected eye. During the afternoon of the third day that the eye had begun to give him trouble I was called in to see the patient. I found very marked swelling of the lids, chemosis, and an enlarged eyeball, due to a participation of the capsule of Tenon. The cornea was a little hazy, and the pupil presented that peculiar yellowish-white reflex which is so characteristic of the presence of pus in the interior of the eye, especially in the vitreous humor. The pain had now become intense, and the temperature was very high; he had marked chills during the night and morning preceding my visit, and had not the slightest perception of light in this eye. I knew that the vision could never be restored, and as the poor fellow suffered so intensely, I thought that enucleation of the eye would be the shortest way of giving him relief. However, the surrounding parts of the eye, in fact all the contents of the orbit, were so inflamed that I decided not to do it. I ordered hypodermic injections for the relief of the pain, and had hot applications made to the eye. Atropine had been used previously, but had utterly failed to diminish the pain, and I had it discontinued. This treatment by hypodermic injections and the local applications of hot water was kept up for three days, when the presence of pus in the conjunctival sac indicated an opening of the abscess. Thus pus had made its way to a point near the upper and outer part of the eye in the sclero-corneal region. The pain soon subsided, the inflammatory symptoms improved, and a short time later I discontinued my visits. However, the patient never regained the slightest amount of vision and the eye became phthisical.

Case II.—A carpenter, aged thirty-six, living in one of the small neighboring towns. He hit his right elbow, an insignificant contusion resulting. He did not pay much attention to the injured arm at first, but soon the inability to use it, the great increase of the swelling of the elbow-joint, and great prostration induced him to consult his family physician, who applied a bandage and ordered rest and tonics However, the patient did not do well, and had to take morphine constantly to relieve the constant pain in the arm. About two weeks had passed in this way when the doctor began to perceive a swelling of the right parotid gland, which was treated by iodine application. About a week later the right eye began to be painful, and to look red. The pain was deep-seated and of a tearing, lancinating character, and the sight of the eye became rapidly poor, so that he could hardly see the light of a lamp. As the pain in the eye became more and more severe, I was called upon to remove the eye, especially as the patient threatened to commit suicide, unless he could get relief. When I examined the patient I found a moderate amount of exophthalmos, some hypopyon, and the vitreous humor full of pus. The eyeball was very sensitive to the touch, and he could not see the brightest light with this eye. The other eye was normal and had good vision, although the patient pretended that he could not see near as well with it as he had before the other eye became sore.

The patient was very weak, and although he had not much fever, he had a very high pulse. The parotid gland was very large, but had evidently not suppurated. The elbow was still red and swollen, and was discharging a moderate quantity of fetid pus. I removed the eyeball, which I found to be almost completely changed; the choroid, retina, and the ciliary body were all infiltrated, and the iris was almost entirely adherent to the periphery of the lens. There was only a moderate amount of bleeding after the operation, and the family physician allowed this to continue for several days. The orbital tissues appeared normal, at least the tunica vaginalis of the eyeball was not so much changed as I had expected to find it. The patient appeared to rally soon after the operation, so the doctor of the place informed me; but some two or three weeks after the enucleation the headache returned worse than before, so that for several weeks the patient had to take anodynes constantly; he became weaker and weaker, and died in a comatose condition, from what the doctor supposed to be a cerebral abscess. An autopsy was not allowed by the family.

These two cases were evidently both of the metastatic, or as they are called by some writers, embolic variety of

purulent choroiditis, and they were both, it is safe to assume, due to the transmission of pathogenic microbes from the purulent inflammation of the elbow or knee, respectively.

The treatment of these cases ought not to vary from that usually resorted to in purulent affections of the interior of the eyeball. In milder cases atropine and hot compresses and anodynes, if necessary. In the severer cases of this affection either a free incision, evisceration, or entire removal of the eyeball may become necessary. Although the removal of an eyeball with panophthalmitis is not considered safe, yet if it appears that the capsule of Tenon is not very much involved, I consider the operation indicated; for I do not think that either the death of the patient on whom I operated, or the supposed cerebral abscess, had any direct connection with this operation, and that the patient would have died, operation or not; and that the operation gave him, at least, great comfort during the two weeks of his life. As long as the opportunities for the absorption of the septic material remain favorable, abscesses are liable to form in any part of the body, and the life of the patient is in constant danger.

I have become quite enthusiastic of late about the good effects of a corrosive sublimate solution applied to the eye by means of an eye-cup for several minutes at a time, and using it in the strength of 1 to 5,000, or 1 to 8,000, if the former should prove a little too irritating. I have used this remedy for wounds of the cornea with suspiciously infiltrated margins, in cases of deep-seated infiltration of the cornea, and in cases of obstinate plastic and purulent iritis, with so much success that I should not hesitate to use this germicide externally as well as internally in cases of this kind of choroiditis.

Does not an atropine solution reach the interior of the eye by osmosis very easily? Why should not a corrosive sublimate solution penetrate sufficiently to exert a beneficent influence on a purulent disease of the deeper-seated membranes of the eye, which we cannot reach in any other way? And why should not the internal use of the drug, which is supposed to have such a beneficial effect on the microbes of diphtheria, have likewise a good effect on this disease of the choroid, as well as on the original purulent disease which gave rise to it? I look upon the bichloride of mercury as the great remedy of the future.

140 Madison Avenue.

A MODIFICATION OF TEAL'S RECTANGULAR FLAP OPERATION IN THE AMPUTATION OF THE EXTREMITIES.

By ROBERT J. REED, M.D.,

VISITING SURGEON TO THE CHARITY HOSPITAL, WHEELING, W. VA.

In the amputation of the extremities, "save as much as possible" is a well established rule, with few exceptions, and the preservation of the articulations is a question of paramount importance. The suggestion of any method working to these ends needs no apology.

It is true in many injuries, especially in crush wounds, necessitating amputation, that upon one side a greater amount of sound tissue is found than upon the other. This condition suggests Teal's operation. But by this method, in order to secure sufficient covering for the stump, the long flap must be equal in length to half the circumference of the limb at the point at which the bone is to be divided, and the short flap one fourth this circumference. Both are rectangular in shape and equal in breadth to half the circumference, so, even by this plan, considerable of bone or an articulation may have to be sacrificed.

In Teal's method the ends of the long and short flaps are united. The modification suggested consists in a different way of coaptating the edges, by which shorter flaps will suffice. Integument and subcutaneous tissue alone is used, a modification recommended by Lister. The long flap is but one-fourth the circumference of the limb in length and half the circumference in breadth. The short flap is of the same breadth, but need not extend in length beyond a level with the bone. With this amount of integument the stump can be covered by bringing the sides of the long flap into coaptation with the end of the short one. Since the length of the long flap equals one-half the width of the short, the two sides meet in the centre of the short flap, and half the end of the long flap falls against the other half, which effects a complete covering of the bone.

The decided advantage of this method under certain conditions can be better appreciated by recounting a case of reamputation of the leg. The primary amputation had been through the tibia at the lower margin of the tubercle. The anterior flap had sloughed away to a level with the ends of the bones. The posterior flap had retained its integrity, but its length was less than one-fourth the circumference of the limb at that point, until much of the remaining muscular tissue had been cut away and the head of the fibula removed. Then by giving it a rectangular shape and bringing its two right-angled corners up to a central point in front, as shown in the illustration, the stump was covered.

By any other method more bone would of necessity have been sacrificed, which would have involved an invasion of the joint. The result was a firm stump and a saved joint.

Progress of Medical Science.

Suppurative Cholecystitis.—Dr. Lindner (*Berlin. klin. Woch.*, No. 11, 1892) records an interesting case of operation on the gall-bladder. The patient—a woman, aged twenty-eight—had previously suffered from perityphlitis and recovered. Symptoms pointed to suppuration of the gall-bladder, and an incision made along the outer margin of the rectus muscle, on the right side, brought the gall-bladder, which was greatly distended, into view. Upon opening the organ a quantity of pus and a good-sized calculus escaped. The walls of the bladder were sutured to the abdominal wall, and the cavity was thoroughly washed out and drained. After a few days bile escaped instead of pus, and recovery was complete after five weeks. Three months later, however, the patient returned complaining of colic and other symptoms as before. A fistula had remained after the first operation, and still discharged bile. On enlarging the fistulous tract and passing the finger, a calculus was discovered in a blind pocket, but separated from the canal by what seemed to be a membrane. The liver and gall-bladder were exposed by an abdominal incision, and it was then discovered that the latter was divided into two chambers by cicatricial tissue. The return of symptoms had been caused by impaction of a calculus in the opening between the two cavities, and its removal was found quite difficult. Recovery soon followed the second operation, and after it the previously existing fistula closed.

Primary Urethral Tuberculosis Simulating Stricture.—Dr. Fenwick (*British Medical Journal*, May 28, 1892) believes a primary urethral deposit to be most rare. It should afford, however, a better prognosis here than in any other part of the tract, for the constant passage of urine over the surface sweeps away the irritating secretions. Although he can only point to one case of primary disease—and that he mistook for stricture until

he had examined with the electric urethroscope—yet he has had several cases in which the urethra was invaded from foci in the prostate and bladder. A consideration of these permits him to state that when tubercle affects the bulbo-membranous section of the canal, it is very likely to be mistaken for stricture, for the swelling offers a decided obstruction to the exploring *bougie à boule*. You recognize the difference between this swelling and stricture by the extraordinary amount of pain which is caused by the most delicate instrumentation, and this even after a strong solution of cocaine has been previously applied. The surface bleeds on the slightest touch, and severe rigors often follow any examination. These are not only alarming, but are positively dangerous when the kidney is latently affected. A perineal fistula—Nature's attempt at a radical cure—often forms rapidly in the post-scrotal region. All manipulation is out of the question, but much good may be done by iodoform urethral bougies gently insinuated into the deep urethra, the general health being at the same time well supported.

New Method of Examining Specimens of Blood.—A method of making permanent preparations of blood has recently been described by Dr. R. Muir, in the *Journal of Anatomy*, which promises to be of great use in clinical investigation. The specimens thus prepared can be preserved indefinitely, and compared with others obtained from the same patient at subsequent periods. The method is quite simple. The films are prepared on coverglasses in the usual way, and, before they have time to dry, are placed in a saturated aqueous solution of corrosive sublimate (to which a little common salt may be added) for half an hour. The corrosive sublimate is then washed away with a three-quarter per cent. solution of common salt, and the film is further hardened by a few minutes' immersion in methylated spirit, and then absolute alcohol. The specimens can then be stained by the ordinary reagents, very good results being given by double staining with eosine and hæmatoxyline, the red corpuscles being stained by the eosine, while the nuclei of the leucocytes are prominently revealed by the hæmatoxyline.—*The Lancet*, May 28, 1892.

Tetanus Immunity.—Dr. Hoegh, in the course of an article on tetanus (*Northwestern Lancet*, June, 1892), says: "Modern investigators have discovered that there are certain animals which have a more or less pronounced immunity against certain bacterial diseases, and that this immunity is due to the presence in the blood-serum of a certain chemical compound belonging to the group of the albumins. Thus the rat possesses immunity against anthrax, the dog against tetanus, the field-mouse against septicæmia. The chemical substance in the serum of these animals is antidotal to the poisons produced by the respective bacteria. But this chemical compound can artificially be produced in animals, and Behring and Kitasato have in this way succeeded in making animals immune to tetanus. But not only this, the serum of animals made immune does not only, when injected into other animals, confer immunity against subsequent inoculations, but has more or less curative effect when the animals already have become subject to the developed disease. Tizzone and Centanni isolated from the serum of such immunified animals the anti-tetanic principle, and Tizzone claims to have used it with success in the human being. It was with this anti tetanic principle that several cases referred to were successfully treated."

Paroxysmal Tetanic Spasm in Chronic Hydrocephalus.—Dr. Carter presented part of a brain taken from a girl aged twelve years. When seven months of age she had frequent convulsions associated with retraction of the head, and was ill for thirteen weeks. Was then fairly well until eight years of age, when she had a severe headache, followed by insensibility which lasted twelve hours. Three months before death the headache (generally occipital) returned, with frequent vomiting. In spite of this she was not ill enough to give up attendance at school for two months. She then became subject to paroxysmal convulsive attacks, in which the head was retracted and the whole body bent backward, and accompanied with severe pains in the back of the head. The attacks lasted from one to three hours and recurred daily till the time of her death. There was marked double optic neuritis. Cerebellar tumor in the median lobe was diagnosed, but at the post mortem nothing was discovered beyond evidence of chronic meningitis about the neighborhood of the medulla oblongata, with firm adhesion of the latter to adjacent parts, and hydrocephalic distention of all the ventricles.—*The Birmingham Medical Review*, June, 1892.

The Bacillus of Eclampsia.—Dr. Gerdes, in the pathological department of the University at Halle, has found a bacillus in the liver, lungs, kidneys, and blood of a severe case of eclampsia. Cultures of this bacillus, when inoculated in rats and mice, cause shallow respiration, coma, subnormal temperature, and in the mice convulsions. It is very virulent, causing death in a short time. In guinea-pigs intra-venous injections caused convulsions, intra-peritoneal did not. The bacilli were found often in the form of bacillary emboli, the starting-point of which was probably a focus in the placenta.—*Boston Medical and Surgical Journal*, June 2, 1892.

Soporific Effect of Sulphuretted Hydrogen.—At a meeting of the Greifswald Medical Society, Professor Schulz gave an account of some experiments on animals to determine the soporific effect of sulphuretted hydrogen. He put the subjects of the experiment under a large bell-jar, the air of which was charged with various definite proportions of sulphuretted hydrogen. In some cases restlessness and asphyxia were produced, in others sleep. Rabbits appeared to be better able to resist the effects of the gas than other animals, as they did not fall asleep until after they had been half an hour in an atmosphere containing from 0.27 to 0.44 per cent. of sulphuretted hydrogen. Dogs required from 0.07 to 0.17 per cent., and cats from 0.09 to 0.1 per cent., sleep coming on in about an hour. When a very small quantity of sulphuretted hydrogen was present the animals became drowsy. The new hypnotic drugs—sulphonal, trional, and tetronal—doubtless give off sulphuretted hydrogen in the body, for if they are put into a flask along with some fresh liver tissue at a temperature of 99° F. this gas is evolved, the reaction appearing to be even more energetic when the liver has just begun to putrefy.—*The Lancet*, June 4, 1892.

Flatulence in Stomach Disorders.—Dr. Perujo believes that eighty per cent. of dyspeptics suffer from flatulence, and that in twenty per cent. of cases it is very severe and quite alarming. The origin of the gas may be from the atmospheric air, from the diet, from the blood by exosmosis, or from decomposition of the fecal matter. Chemical analysis of the gas reveals oxygen, azote, hydrogen, carbonic acid, protocarbonated hydrogen, and sulphuretted hydrogen. Pain is the chief complaint, and at times it is so severe as to simulate poisoning. As to treatment, regimen plays an important part. The patient must masticate all food laboriously, must lead an active life, and regulate the hours for taking food with much care. Abdominal massage acts beneficially by stimulating the digestive organs. Applications of heat give good results. This can be done by the use of poultices or the hot-water bag. The sulphites and hyposulphites, the bicarbonate of soda, soda, charcoal, bismuth, carbonic acid, creosote, etc., are usually employed with success, but the salts of soda, bismuth, and charcoal do not in any sense absorb the gases. Anti-spasmodics and aromatics are not to be neglected, while the rectal tube through which the gas may escape, electricity, and capillary puncture have their uses in certain cases. In the author's opinion there is no lasting success without the most rigorous dietetic measures.—*Rev. Intern de Bibl. Med.*, April, 1892.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, August 27, 1892.

PROGRESS OF THE CHOLERA.

WITHIN the confines of Russia there has apparently been but slight advance of the cholera epidemic during the past week. The reports from that country are, however, so conflicting that it is difficult to estimate correctly the extent of the ravages caused by the disease. Even if we could be confident that the official reports were strictly honest, the figures would necessarily be incomplete, for they are sent to St. Petersburg from the infected regions partly by telegraph and partly by mail, and the confusion as to dates that results is very great. Then there is no reliance to be placed upon the local officials, who, for one reason or another, often conceal the actual number of cases. The total number of new cases reported daily is in the neighborhood of six thousand, while the deaths average about half that number.

But what is of much more vital interest to this country is that the disease has broken out among the Russian refugees in Hamburg and also in Havre. The first cable reports brought the news that there were several cases of "cholerine" at Hamburg, but an investigation by the American Consul in that city brought to light the fact, already suspected, that the disease was true Asiatic cholera. The Consul at once informed the Washington authorities of the appearance of the disease at Hamburg, and the latter have warned the health officers at the different ports. In view of the fact that hundreds of immigrants are brought direct from Hamburg to this country every week, the majority of them to New York, it is not at all improbable that some cases of the cholera will appear here. Indeed, it is thought possible that the steamship La Touraine, now on the way to this city from Havre, may have some cases aboard, for the American Consul at that port has cabled the authorities here to be on the lookout for the steamer. There is, however, as we have before said, no ground for alarm, even should a few cases reach quarantine. There is urgent necessity for more than usual vigilance on the part of the health officers of the port and of the city, but they are alive to the danger, and we have every confidence that they will be able to cope with the disease should it make its appearance here. And the same, we are happy to believe, may be said of the Marine Hospital Service and of the quarantine authorities at other threatened ports on our coast. It is reported from Berlin that Dr. Koch has been sent to Hamburg to confer with the authorities there in regard to the most effective measures necessary to combat the disease. This sounds somewhat like closing the barn-door after the theft of the horse, but we may still hope that it is not too late to do something in the way of staying the further advance of the disease.

The United States Consul at Teheran cables, under date of August 22d, that there are four hundred deaths daily from cholera in that city, and that many cases are under treatment at the American hospital there.

EXOPHTHALMIC GOÎTRE.

CERTAIN points of special interest concerning this disease are accentuated in a preliminary note by Dr. Louise Fiske Bryson, in the *Post-Graduate*, July, 1892. Up to the present time, for lack of sufficient and minute investigation that is possibly due to preconceived opinion as to origin, exophthalmic goître still remains a "mysterious malady," as Gowers puts it, a train of distressing symptoms that may be relieved in turn, and may also disappear spontaneously. Under favorable circumstances, according to Charcot, the disease tends to recovery in from one to five years. A good working hypothesis is to consider it a disorder of nutrition, respiratory in its first manifestations and digestive afterward, acted upon later by some special exciting cause, as infection, trauma, strain, or shock.

The treatment securing best results has been a combination of mechano-hydrotherapy and rest and exercise, together with the strictest possible attention to details of dietetics and general hygiene. The drugs that have been most helpful are nux vomica, arsenic, and digitalis sparingly. Moderate altitudes instead of the sea-level are usually the best health-resorts for sufferers from this disease. Hours of rest and exercise must be prescribed, the kind and amount, and never left to the patient's discretion.

In exophthalmic goître, there are always present some alterations in respiratory processes. Respiratory expansion is lessened in more than half of all cases that come under observation. Respirations are increased from twenty to thirty a minute. Increasing chest expansion is of great importance, as the physiology of respiration includes an influence upon the heart itself, upon the pulse, upon blood-pressure, and upon the pulmonary circulation. To secure normal respiration, a somewhat novel plan of treatment suggested itself to the author of the preliminary note.

Deep respiratory movements by means of a variety of exercises that raise the arms, expand the chest, and cause deep and regular breathing, have been secured through the agency of an apparatus called the Respirator, invented by Dr. Charles Fayette Taylor, which embodies in mechanical form Ling's principles of artificial respiration. The patient sits in a large chair or couch with a jointed, movable back, grasping with the hands padded handles suspended from long levers placed at the back of the apparatus. These come to the patient's side in such a way that, when grasped by the hand, the body is in perfect repose. Steam power is now turned on, the levers rise, the arms are drawn upward, the muscles of arm, chest, and abdomen put upon the stretch, while the upper part of the cushioned back moves down and the chest is

arched forward. The levers then descend, muscles relax, and the chest returns to its first condition. Respirations adapt themselves to the motion of the levers. When they rise, a deep and full inspiration is taken, the air being forced—though in the gentlest manner—to enter into and distend the alveoli. When the levers return, expiration is accomplished.

Improvement is rapid, for the chief value of mechanotherapy in nervous or general constitutional disorders is to regenerate the mass of blood as a whole, to combat individual symptoms, and to favorably influence the mental state. The Respirator possesses certain advantages over more active and voluntary movements. It exercises without fatigue, without strain upon the will-power, and without the intervention and activity of another's personality. The action is entirely passive, as it is steam, an unseen and remote agent, that raises and drops the levers without noise, bustle, or conversation.

The effects of systematized respiratory movements, as thus brought about, are, first, to increase the capacity of lungs for air; second, to strengthen the elastic tissue of the alveoli; to open up inactive air-cells; to promote free expectoration; to loosen adhesions (pleuritic, etc.); to stimulate pulmonary circulation, nourishing the lung-substance; to rectify errors in the general circulation; and to increase the aëration of the blood, thus nourishing the tissues and increasing metabolism. In the treatment of circulatory disorders, many of Oertel's arguments to prove the efficacy of mountain climbing apply also to the use of artificial respiration, according to Ling's principles; for Oertel's aim is to reduce the quantity of fluid in the body, to oxidize the accumulated fat, to effect a balance between the arterial and venous systems, and to strengthen the heart-muscles.

A MEDICAL DEFENCE OF THE OPIUM HABIT AMONG EASTERN NATIONS.

The *Indian Medical Gazette* publishes a number of articles from native and local physicians, detailing their experience and giving their opinions as to the use of opium by the inhabitants of India. The *Gazette* says editorially: "The terrible pictures which they [the opponents of the use of opium] draw regarding the effects of opium, are not recognized by medical men in India, and they seem to us as far from the reality as many a Hindoo's view as to the injurious results following from the indulgence in that beverage which "cheers but not inebriates."

"Experience proves it is useless to attempt to make people better by legislation, and moreover we hold that the moderate use of opium in an Eastern country will have the same calmative and stimulant effects as the use of tobacco, and that the excessive use of tobacco is almost as productive of mischief to the human constitution as that caused by the abuse of opium. Observations in this country demonstrate that moderate opium eating or smoking, far from being that unmitigated evil which those unfamiliar with the subject or with the people and their customs maintain it to be, is, on the contrary, a solace and mainstay to many who otherwise would be unfitted for the battle of life."

The proposal to abolish the use of opium in India except for medical purposes, would, in the *Gazette's* opinion, be undesirable for several reasons: "Firstly, because opium in moderation does no harm; secondly, because it does good to a large proportion of those inhabitants who live in malarious districts; thirdly, in some parts of India it bears an important part in some of the ancient customs of the people; and fourthly, because the attempt to carry out such an abolition would create a vast deal of suffering and hardship on the people without bestowing upon them any corresponding benefit."

Dr. Crombie collected the statistics of the asylums of Lower Bengal for the ten years 1881 to 1890, with the following result: Of the 2,202 admissions, 641, or 29.1 per cent. were gunja smokers, 117, or 5.3 per cent., were spirit drinkers, and 8, or 0.36 per cent., were opium eaters. Figures from the Asylum of the Bombay Presidency give similarly low results for the opium eaters.

On the whole, the opinion of Indian physicians, according to the *Gazette*, is against the attempt to restrict opium eating. It must be said in comment on this, however, that at least one of the physicians who make a favorable report is confessedly an opium eater himself. The very high percentage of cases of insanity due to gunja smoking (cannabis indica), shows that all popular narcotics of the East are not harmless.

THE LONGEVITY OF ACTORS.

It is pretty well established that brain-workers who live anywise temperately are long-lived. But it remains to be shown that actors and actresses have the same happy characteristics. There is a prevalent impression among the fraternity that all good actors die early of paresis, and of course no account is taken of the poor ones. A Paris correspondent of the *Manchester News* now affirms that Parisian actors and actresses, at least, are long lived. He cites fourteen instances of popular artists who have reached or passed the age of seventy. Of course this is hardly conclusive, yet there can be no doubt that many of the really great actors have lived long lives, for such persons must be naturally endowed with great vitality in order to do their work, and they must necessarily conduct their lives with some regularity. The young geniuses who burst upon the public and win their laurels early, are generally overcome by their success and succumb to wine, women, and excitement.

Post-mortem Delivery.—A remarkable case connected with the post-mental state is reported by Dr. Bleisch. A woman at term died during labor from some cause or other before delivery was completed, in the presence of the midwife. The doctor, who arrived two hours later, verified the condition of things, but did not extract the child, and the corpse was laid in the coffin five hours after death, without anything unusual being noticed by those present. Three days later the coffin was reopened for the purpose of performing a necropsy, when it was found that the child had meanwhile been expelled, the womb being everted and protruding beyond the genitals. The connection between fœtus and placenta was intact. How such an event can come about, whether merely in consequence of the formation of gas in the abdominal cavity or by the occurrence of post-mortem contractions of the uterus or otherwise, it is impossible at present to state.

News of the Week.

Disappearance of a Naturalist.—Mr. Hermann Foll, a well-known zoologist, started in March last upon a scientific expedition in the Mediterranean. He sailed from Brest in the steam yacht Aster on March 19th. The yacht was sighted eight days later, but since that time all trace has been lost of her, and nothing has ever been heard of Mr. Foll and the crew.

William Dalla Husband, F.R.C.S., the leading surgeon in York, England, died in that city recently, in his seventy-sixth year, after a long and painful illness.

Dr. John Drysdale, one of the leading homœopathic physicians of London, died on August 20th.

Dr. Clarence O. Taylor, of this city, died on August 19th, of pulmonary hemorrhage. He was on his way to see a patient the evening before, when a profuse hæmoptysis came on, and it was found necessary to take him to the New York Hospital. Dr. Taylor was a graduate of the Bellevue Hospital Medical College in 1879, and was a member of both the New York County Medical Society and the New York County Medical Association.

The Tri-State Medical Society will hold its fourth annual meeting in Chattanooga on October 25, 26, and 27, 1892. The three States, from the citizens of which the membership of the Society is recruited, are Alabama, Georgia, and Tennessee. The secretary of the Society is Dr. Frank Trester Smith, of Chattanooga, to whom application for membership should be sent.

An International Congress of Criminal Anthropology was held in Brussels, under the patronage of the Belgian Government, August 7th to 14th. The President of the Congress was Dr. Lemal, director of the State Lunatic Asylum at Mons.

Sir Richard Owen, K.C.B., the well-known anatomist, is reported to be failing in strength, although free from any actual disease. His friends feel considerable anxiety about his condition, as he is eighty-eight years of age, and they fear his recuperative powers will prove insufficient to combat the decline of strength.

A Permanent Home for the British Medical Association.—At the annual dinner given during the recent meeting of this Association at Nottingham, Dr. Withers Moore, President of the Council, announced that the Council intended at no distant date to set aside the sum of £50,000 or £60,000 for the purchase of a site and the erection of suitable buildings in London, to serve as a permanent home for the Association.

Mr. Samuel Armstrong Lane, one of the founders and for many years surgeon of St. Mary's Hospital, London, died in that city recently at the age of ninety years. He retired from practice many years ago.

Professor Virchow has been elected Rector of the University of Berlin for 1892–93. The University would doubtless have been honored by this appointment many years ago, had it not been for the prejudice existing in certain circles against the eminent scientist for his well-known radical tendencies in politics.

The International Congress of Gynecology and Obstetrics will be held in Brussels, September 14–17, 1892. The subjects proposed for discussion are pelvic suppurations, extra-uterine pregnancy, and placenta prævia. The programme of entertainments is an attractive one, and comprises concerts, receptions, a gala night at the Opera, a banquet tendered by the Belgian Society of Gynecology and Obstetrics, and various excursions. All communications relative to the Congress should be addressed to the Secretary-General, Dr. Jacobs, 12 Rue des Petits-Carmes, Brussels, Belgium.

Dr. Valerian Podrowsotski, of Kazan, died there recently at the age of sixty-nine years. He was originally a lawyer, and did not receive his medical degree until he was fifty years old. He was Professor of Pharmacy and Pharmacognosis in the University of Kazan.

Small-pox in Boston.—A case of small-pox was recently discovered in the person of a Russian girl, in Boston. This is the first known case of the disease in that city in over two years.

Dr. Ignatz Roth, of Vienna, has recently died in that city. He was a member of the Dermatological Society, and was the author of several monographs relating to skin diseases and syphilis.

The Chicago Vegetarian Society had a celebration the other day, and feasted on cucumbers, cabbage, water melons, and other succulent products of the vegetable kingdom. One of the members defined the position of the society and declared that the eating of animal flesh was but one degree removed from cannibalism, and in many respects equally as revolting. "Meat," he said, "is the cause of more crime than alcohol, which is a vegetable substance. The eating of flesh makes men bloodthirsty and cruel, and for that reason is an offence. If no meat were eaten the world would be much further advanced in civilization, refinement, and culture than it is at present."

Hydrophobia in Massachusetts.—Some alarm has been aroused among timid people in Eastern Massachusetts by the published accounts of numerous cases of rabies, and the newspapers began to talk of an "epidemic of the dread disease." Most of the cases reported, however, were spurious, and the State Board of Health declares that there have been but a little over one hundred deaths from hydrophobia in Massachusetts in the last half-century.

Dr. J. M. Deaver died at his home near Lancaster, Pa., on August 22d, after an illness of five weeks. He was seventy years of age. He was a member of the Maryland and Pennsylvania State Medical Societies.

Glanders in London.—It is said that glanders has become almost epidemic among the horses in London, and the authorities are so alarmed at its spread that they have issued special instructions looking to the complete isolation of horses that are suspected of being infected with the disease, and the slaughter of every animal that is known to be suffering with it. Every horse in the city is being strictly watched, and even the public drinking-troughs have been closed to prevent the contagion spreading by this means. The latter action has called forth numerous protests from veterinary surgeons and others, who maintain that more harm will result to the horses from the deprivation of water during the hot weather than could possibly result from leaving the troughs open.

But drivers could carry pails in their wagons which could be filled from any hydrant, thus doing away with all danger of infection. The wife of a hostler has died from glanders, and several other cases of the disease have been found among the families of stablemen.

Hot Weather in Europe.—The cable brings report of unusually hot weather all over Europe, and many cases of sunstroke have occurred in the large cities, and among troops who have been forced to perform their ordinary evolutions under a mid-day sun.

Professor Da Costa has withdrawn from all teaching connection with the Jefferson Medical College of Philadelphia. Since he resigned from the Chair of Practice of Medicine, he has been holding clinical lectures at the College.

Dr. Joseph Colvis, a well-known American physician in Paris, died in that city a few days ago. Dr. Colvis was of African descent, and was born in New Orleans in 1831. At the age of eight years he left for France with his relatives, and was placed in the Lycée Bonaparte. Here he received the degrees of B.A. and B.S. He then studied medicine, and after serving for some years as interne in the Hôpital Saint-Louis, was graduated as doctor in medicine. He was repeatedly decorated by the French Government for public service rendered in the line of his profession, notably during the Franco-Prussian War, and a few years ago was awarded the Cross of the Legion of Honor. He never resigned his American citizenship.

Sisters in the Paris Hospitals.—A meeting was held recently in Paris, with the object of demanding the reinstallation of Sisters of Charity in the public hospitals. The opponents of the measure were present in force, and the meeting was a most tumultuous one, although the promoters of it succeeded in carrying their resolutions.

End of a Libel Suit.—The *Bosphore*, a newspaper of Cairo, has been condemned to pay $5,000 to Dr. Milton, an English physician in the native hospital. The journal had attacked the English physicians of Cairo most savagely, and was sued for libel by Dr. Milton.

Cure of Myxœdema.—Dr. Wallace Beatty, of Dublin, has reported a case of myxœdema cured by massage and the injection of the juice of the thyroid gland of a sheep.

The Registration of Prostitutes.—Authorities differ widely as to the benefit derived from the registration and examination of prostitutes. Only recently, at the meeting of the Public Health Section of the British Medical Association, Dr. Drysdale contended that syphilis was less prevalent in London, where no restrictions are put on prostitution, than in Paris. Yet statistics, as far as they prove anything, do certainly point to the value of registration in restricting the spread of venereal disease. The *British Medical Journal* states that among 2,941 registered prostitutes in Paris, arrested for various reasons in 1891, 251 were found to be suffering from venereal disease. Of 2,637 clandestine prostitutes arrested under similar circumstances, 1,153 were infected. The proportion of disease was therefore about 8½ per cent. among the registered women, as against 43 per cent. among the clandestine prostitutes. In Brussels, where the regulations are very strict, the proportion of disease is somewhat less among the registered women, but among the clandestine prostitutes it has recently increased to such an extent that an additional ward has had to be opened in the St. Pierre Hospital for their reception.

The Digestibility of Various Kinds of Cheese has been recently tested by a German chemist, who placed the samples in fresh gastric juice. Cheshire and Roquefort cheese took four hours to digest; Gorgonzola and Neufchatel, eight hours; and Brie and Swiss cheese, ten hours.

Longevity among Indians.—From a recent census report on the Six Nations in New York State, we learn that, among the 5,239 still remaining on the reservations, the enumerators found 6 persons over ninety years of age, 26 between eighty and ninety, 64 between seventy and eighty, and 173 between sixty and seventy years. The age of Governor Blacksnake, who died on the Alleghany reservation in 1859, was variously and extravagantly estimated at from one hundred and seventeen to one hundred and thirty years. There is no doubt, however, that he was over one hundred years old.

Greenbacks and Bacteria.—Drs. Acosta and Rossi report, in an Havana journal, the results of some bacteriological examinations of bank notes made by them. They examined two bills that had been in circulation for some time, and found them loaded with germs of various kinds and all degrees of malignancy. The two bills, which together weighed about a gram, say fifteen grains, contained, it was estimated, between nineteen and twenty thousand microbes. Cultures were made from the scrapings of the notes, and these were injected into the peritoneal cavity of rats and guinea-pigs, most of which died within twenty-four hours, the post-mortem examination showing signs of peritonitis and congestion of the liver and kidneys.

Electrocution.—In an article in the *Lyon Médical*, M. A. Lacassagne discusses at some length and quite intelligently the subject of execution by electricity. He thinks that it is not so sure a means of taking life as its advocates maintain, and quotes with approval the remark of d'Arsonval, that "the American physicians would not dare practise artificial respiration on their victims." He believes, however, that this mode of execution is of service, as it affords an opportunity to study the physiological mechanism of death by electricity, and gives hope of an early solution of the problem of fulguration, concerning which there is at the present day so much that is incomprehensible and apparently contradictory.

An Innuendo.—The circular announcing the forthcoming meeting of the Mississippi Valley Medical Association says, that the Society "possesses one great advantage over similar bodies, in that its organic law is such that nothing can be discussed during the sessions save and except science," and thus "precious time is not allowed the demagogue or the medical legislator."

Colored Morphine.—It has been proposed by a German physician that morphine be always stained a bright red with aniline, in order to diminish as far as possible mistakes in compounding.

Sir Lyon Playfair, the well-known chemist, has recently been raised to the peerage.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, held at Nottingham, July 26, 27, 28, and 29, 1892

SECTION ON SURGERY.

FIRST DAY, WEDNESDAY, JULY 27TH.

The President's Address.—MR. JOHN CROFT, F.R.C.S., in taking the chair, expressed his high appreciation of the honor of presiding over the deliberations of the Section. He said that one special subject had been selected for discussion at each session of the Section.

Surgical Treatment of Pleural Effusions.—This was the subject for the first day. The surgical treatment of these affections had now advanced to such a point that certain formulæ were generally admitted: 1, That early evacuation is the best principle to act upon; 2, that the exclusion of air where practicable and the observance of aseptic or antiseptic *technique* should be rigidly observed; 3, that complete and perfect drainage of the cavity under treatment is essential, including counter-openings and large openings into the pleura or other pus-holding cavities; 4, that large cavities require adequately large openings; 5, that ribs and periosteum, intercostal vessels and nerves, may be largely excised with advantage immediate and prospective, so long as ordinary precautions are observed; 6, that lack of early and adequate operations are important causes, though not the exclusive causes, of delay in the closing of cavities; 7, that lung abscesses and gangrenes and bronchiectatic cavities, with certain obvious exceptions, are amenable to surgical exploration and treatment; 8, that hydatid cysts in the lung or pleura may be successfully extracted or otherwise cured by thoracotomy.

Among the causes that hinder success in surgery of the chest is the difficulty in many cases of exact diagnosis. Sometimes preventable procrastination delays surgical interference. Rigidity of the walls of the cavity makes healing difficult, and attempts to obviate this by removing large portions of the bony wall are not altogether successful. Mr. Croft asked whether it might not be justifiable to remove the collapsed lung (which he thought kept up the pleural discharge) by dividing it near the root, in cases where it was spoilt as an organ.

Surgery of the Liver and Gall-Bladder.—The speaker then referred to the achievements of surgery in this department, which would be the subject for discussion the second day. There were questions still unsettled, such as the treatment of hydatids of the liver that had opened or were likely to open into the chest; the question of early operation in cholelithiasis; the desirability of suture of the gall-bladder and closure of the wound; the treatment of gall-stone when impacted in the duct and not to be got at from the bladder; and finally, the question of ligature of the duct and of cholecystectomy.

The Treatment of Spinal Abscess would be the third subject to be discussed by the Section, and much good might be hoped to result from the consideration of the different modern methods of treatment.

Surgery of the Thorax.—MR. RICKMAN GODLEE opened the discussion. In cases of empyema he had found that the best place to incise the pleura was over the ninth rib behind, just in front of the lower angle of the scapula. This was the last point to heal in empyema. He had often formerly had to supplement an anterior incision by one in this situation; but since he had adopted the posterior incision he had never had to open the pleura elsewhere. He practised excision of a portion of rib as a routine procedure. It allowed free exploration and evacuation, and the drainage-tube was easily retained. It was, however, sometimes needless, as the event proved, but it was impossible to foretell this, and although it slightly prolonged the operation, it did no harm to the patient. If the chest were very full and fears were entertained as to the effect of an anæsthetic, he performed a preliminary aspiration before administering any anæsthetic. In some cases it was advisable to divide and tie the intercostal artery before removing the portion of rib. He advocated the use of a short flanged red rubber drainage-tube of large size, but only just long enough to reach the cavity of the pleura. This should never be shortened, but maintained of the same length until it was removed altogether. The question arose as to how to end a case. The time of removal of the tube would depend on the amount and nature of the discharge. In simple cases he would remove the tube in children after ten days, and in adults after three weeks or more, provided the discharge had become serous.

In operating on a bad case he preferred to place the patient on the sound side on the edge of the table, but if the chest were very full he laid the patient on the diseased side. For simple aspiration no anæsthetic need be given, while for incision slight chloroform anæsthesia was to be preferred, lasting only until the incision and resection were performed. He thought that when the chest was very full, ether was counter-indicated. Double empyema was not very rare in his experience. When of septic origin it was often localized and acute, and it might be necessary to relieve symptoms by operating on both sides at one sitting; otherwise he thought it better to defer the second operation until the patient had become used to the new order of things on the side first operated on. Tubercular disease of the pleura must be treated with great caution. Operations were seldom advantageous, and often fatal. Aspiration and irrigation should be performed by means of two needles, through one of which the morbid fluid should be evacuated, while an antiseptic solution or warm boiled water should be gently injected through the other. In pneumothorax the air should be removed by aspiration. His experience led him to believe that empyema was more often fatal than was generally thought. Shock was sometimes severe after incision, probably due in many cases to hemorrhage into the pleura, which was often more copious than was supposed, and was, he believed, due to yielding of vessels owing to sudden diminution of pressure, just as hemorrhage sometimes occurred into the cavity of an abscess.

Amyloid disease and clubbing of the finger-ends was not so very common with empyema. The speaker had often known these symptoms to disappear after drainage of the chest. It was also remarkable that discharge might continue for years without amyloid disease of the liver and kidneys resulting. He had had one very marked case of lardaceous disease with albuminuria and enlargement of the liver in which, after incision and drainage, the albumin disappeared from the urine and the liver shrunk beneath the ribs.

Abscess of the Lung.—Most of the cases of pulmonary abscess that were brought to him, he said, were bronchiectatic. He had operated on many. One case which was cured died afterward from other causes, and inspection proved the nature of the disease and its cure. The results on the whole were not good. The patients generally improved for a time after incision and drainage, but finally die. The danger of simple puncture was that septic pleurisy might be set up. On making the incision the pleura might be found healthy and non adherent, and when this was opened the lung might fall away out of reach. These dangers were to be prevented by using a needle connected with a good vacuum for simple puncture, and by sewing the lung and pleura to the chest-wall with a full-curved needle before the pleura was opened.

Among cases showing the occasional difficulty of diagnosis, Mr. Godlee referred to one of left empyema and purulent expectorations which was incised, with a fatal end. On inspection, pus in the pericardium and bronchiectasis were discovered. Had these conditions been diagnosed, they might have been treated by drainage from the pleura. In uncomplicated pyo-pericardium he would

tap at the left fifth interspace near the sternum, having, however, regard to the position of the internal mammary artery, and to that of the pleuræ, which, unlike the lungs, are here symmetrical on the two sides.

Mr. Pearce Gould supported Mr. Godlee in his preference for the posterior opening of the pleura at the ninth rib. He considered that removal of a portion of rib should be a routine practice, but, of course, it had nothing to do with the closure of the cavity afterward. He generally irrigated the chest in empyema, at the time of operation, by a very gentle washing out through a small tube, taking care to allow free exit from the wound so that no pressure was caused in the chest. The reservoir should only be raised one or one and one-half feet. He afterward swabbed out the pleura as thoroughly as possible and removed fibrinous and other matters. If the discharge was afterward putrid he repeated the washing out as often as necessary, otherwise he would not do so. He agreed with Mr. Godlee as to the use of a short tube, but a tube that just reached the cavity at first would often, after a few weeks, be too short, and must be replaced by a longer one. He employed a rigid tube for the first few days to dilate the wound. As an anæsthetic he used chloroform, but as little as possible, especially after the skin incision was complete. He agreed with what Mr. Godlee had said as to opening in cases of double empyema, but no unnecessary interval between the two operations should be permitted; a few days was enough. He thought the distinction between local and general empyema was mainly artificial. In all cases of empyema there were some adhesions.

Dr. Newman, of Stamford, speaking of the dangers of irrigation, referred to the case of a medical man who was subjected to frequent washing out of the pleura, and on the seventh occasion died immediately on the introduction of fluid, death being, he thought, due to shock from the impact of the fluid against the pericardium. The post-mortem examination in this case showed the efficient drainage obtained through the posterior incision. Speaking of diagnosis, he said that auscultation was misleading. Breath-sounds might be heard on the affected side when no air entered that lung. Possibly this was due to conduction by the fluid.

Mr. Jordan Lloyd, of Birmingham, said that the practical conclusion he had come to from experience was that the position of the opening and the kind of tube used in empyema cases were not so important. It was, however, most important that the surgeon should know whether the disease was simple (generally acute) or constitutional (generally chronic). The first mentioned commonly ended in cure, the second was rarely cured in children and never in adults. Early diagnosis in pleural effusion was most important. An exploration with a clean hypodermic syringe should be made whenever there was dulness and loss of vocal fremitus on one side of the chest. Auscultation was of little value. He thought the incision in the mid-axillary line on a level with the nipple as good or better than any, whatever might theoretically be the most dependent part of the pleura. Patients generally lay on the diseased side instead of on the back, and hence incision in this situation favored drainage. He preferred a three-and-one-half-inch incision through the soft parts and pleura to a rib resection. What was wanted was room, and it mattered not whether space was gained in a longitudinal or in a transverse direction.

Mr. Charters Symonds, of London, had found free incision generally enough without resection of the rib. He preferred the posterior incision. If the aperture would not admit the finger he removed a portion of a rib. As an anæsthetic he preferred chloroform. If the heart symptoms indicated it he aspirated before operating with the knife. He thought irrigation needless, and that the masses and shreds of lymph did no harm and should be left alone. In a case of double empyema he would open one pleura and aspirate the other. He would ask Mr. Godlee to say how he would treat abscess of the lung when the pleura was not adherent. His experience was that the lung with apparently non-adherent parietal pleura did not collapse on opening the latter.

Mr. Ward Cousins, of Portsmouth, referring to the treatment of empyema complicated with tubercle, said that well-marked tubercle should be left alone if possible. When, however, the fluid was very copious, interference was needed. Localized tubercular empyema was best left alone. Spontaneous opening of a localized empyema through the lung was by no means an unfavorable occurrence. He only irrigated in cases of fetid discharge. He had found simple aspiration to be usually curative in children, incision and rib resection being seldom necessary. In tapping the pericardium care must be taken not to wound the heart, and this was best avoided by the use of a guarded trocar of small calibre, and by not completely emptying the sac at once.

Dr. Eastes, of Folkestone, spoke of the difficulty of diagnosing the situation of subdiaphragmatic abscess, which might be mistaken for pleural effusion. The effect of deep inspiration on the lower limit of resonance was a valuable sign. When pleurisy coexisted, as it sometimes did, it much confused matters. He had found oxygen combined with the anæsthetic of use in bad cases.

Mr. Mayo Robson, of Leeds, said that he preferred the posterior incision and the short drainage-tube. He used cocaine locally instead of a general anæsthetic, when the latter would be dangerous, as in cases complicated by pneumonia of the opposite side. As a rule he did not resect the rib, for this needlessly prolonged the operation. Washing out the cavity he thought was needless, even in very fetid cases, as he found that the discharge soon became sweet spontaneously after incision and drainage. If it were foul afterward he thought very gentle irrigation sometimes useful. In old cases with rigid walls he practised excision of the ribs. In one case he had removed portions of eight ribs, including an inch and a half of the second rib, with a good result. He had done repeated aspiration of the pericardium for large quantities of bloody fluid with success. He would ask why the success attending drainage of the peritoneum in tubercular peritonitis should not be repeated in the pleura by drainage from its most dependent part?

Mr. J. R. Ratcliffe, of Burnley, said that operations sometimes failed through neglect of the fact that the lower limit of the pleural cavity is not the same in empyema as in health, owing to closure of the lower part of the cavity by adhesion of the diaphragm, which sometimes extended as high as the seventh rib. Hence, if incision were made at the eighth rib the matter was not found. In one case he had known an incision to be made through the chest-wall and the adherent diaphragm into the spleen. The syringe should always be used as a guide, and when the effusion was found, the needle should not be withdrawn, but the knife should be passed down beside it until the matter was reached.

Mr. Rickman Godlee, in replying, quoted his colleague, Dr. Douglas Powell, as saying, "when you think you have to deal with an empyema, pocket your stethoscope." He did not think that Mr. Robson's proposal to drain the pleura in tubercular disease was a good one. Suppuration would result in spite of antiseptic precautions. He believed the distinction between local and general empyema was important because of the constitutional effects. He approved, in certain cases, of swabbing out the cavity, but not of repeated irrigation. He thought that when the patient's condition was so serious as to forbid general anæsthesia, cocaine would be equally dangerous. If the chest were so full that anæsthesia was likely to be dangerous, a preliminary aspiration was the best proceeding.

Injury of the Pancreas.—Mr. Jordan Lloyd then read a paper on "Injury to the Pancreas as a Cause of Effusion into the Lesser Sac of the Peritoneum."

The speaker said that the relation of pancreatic cysts

to the lesser cavity of the peritoneum had hitherto attracted little notice, but he believed that many of these cases were due to gangrene of the pancreas and effusion into the lesser sac.

Mr. Lloyd related two cases which had come under his observation, and referred to two other similar ones already published. In these cases there was dulness on the left side and back over the four lower ribs, due to displacement upward of the diaphragm; consequently there was some danger of a mistake in diagnosis, leading to thoracentesis being done for suspected pleuritic effusion.

The following were the speaker's conclusions: 1. That injury may cause such tumors. 2. They are due to the presence of fluid in the lesser sac of the peritoneum. 3. When this fluid is found to possess dialytic properties we may assume that the pancreas is injured. 4. They are not consequently retentive cysts. 5. Diagnosis is possible from the history and symptoms and position and shape of the swelling. 6. Treatment should be by median abdominal incision and drainage.

Cancer of the Rectum.—Mr. Harrison Cripps then read a paper on "Rectal Excisions for Cancer and the Selection of Suitable Cases, and Prognosis." He said that any attempt to make excision the common treatment of cancer on this part would only bring discredit on the operation. In only a few carefully selected cases was operation feasible. Severe operations extending high up were justifiable only when there was a fair chance of completely removing the disease. After partial excisions the remaining morbid growth increased more rapidly than ever. All rectal cancer was glandular carcinoma. The younger the patient the earlier were other organs involved. In examining the patients no anæsthetic was, as a rule, needed. In doubtful cases, however, ether might be given and a more thorough examination be thus made possible. The speculum was of no practical diagnostic value. Cases in which there was a tight stricture with prolapse from above were not favorable for operation. In such cases the finger might be passed into the cul-de-sac on one side and lead to the belief that it had passed the growth, which might be thought not to extend all round the bowel. When the growth was fixed operation was unadvisable.

Favorable cases were those in which the surface of the diseased portion resembled an ulcer and did not extend entirely around the gut, those in which the upper border of the growth could be defined and healthy mucous membrane felt above it, and finally, those cases in which the neoplasm was freely movable, both laterally and vertically. Most cases would come with one or other of these categories. Of four hundred cases which the speaker had seen he had advised against operation in one half. In thirty-eight he had operated by excision and in seventy-six by colotomy; the remainder refused to submit to any operation. He had been able to trace the subsequent course of twenty-eight of these operated cases. In fifteen recurrence was known to have taken place—in one year in ten cases, and between one and three years in five cases one case died without recurrence, and in eleven none had as yet occurred, although one of these was operated on twelve years and several of them three years ago. After operation stricture was likely to occur during the first and second year and was often troublesome, but if properly treated the tendency gradually disappeared. One patient, in which the recto-vaginal septum was involved, had since given birth to a healthy child and had as yet had no recurrence. Contraction was apt to occur after the fourth week. A bougie should be passed and kept in for some hours daily after the first fourteen days. This should be continued for two months, and after that the bougie might be passed at intervals. The mortality, rate of the operation was less than eight per cent., and the result was hopeful in selected cases.

Dr Snow said that severe operations involving resection of the sacrum were not to be recommended, but he thought that some cases were passed over as unfit for operation which might be treated by incision behind and removal or displacement of the coccyx, and by pulling down the bowel and dividing it with the galvanic écraseur. The sacrum should not be removed merely to provide access to the tumor.

Ligature of the Common Carotid and Subclavian Arteries.—Dr. C. H. Marriott read notes of a successful case of ligature of the common carotid and subclavian arteries for aneurism of the innominate artery the size of a mandarin orange, and showed the patient. The wounds healed well. Silk ligatures were used and cut short; no improvement occurred until six months after ligature. A year after, the tumor was not visible but could be felt and was about as large as a walnut. This was about the condition now, two years and four months after operation.

Second Day, Thursday, July 28th.

A Discussion on the Surgery of the Liver and Gall-bladder was opened by Mr Mayo Robson and continued by Mr. Lawson Tait, who gave statistics of his operations on the liver, one hundred and ten in all. Twenty-one of these were exploratory incisions, eighteen hepatotomies, and seventy-one cholecystotomies. Of the cases of exploratory incision four died; of the hepatotomies, eleven were for hydatid disease, one only of which died; three were for cysts of other nature, two were for gall stones, and one for tumor, all of which recovered, and one for abscess, which ended fatally. Of the seventy-one cases of cholecystotomy only four died, besides one which died from malignant disease five weeks after operation, and one case of cancer of the liver, which died on the nineteenth day. Mr. Tait objected to removal of the gall-bladder, and thought that removal of the urinary bladder would not be less justifiable.

Mr. R. C. Chicken said that free incision was the adequate treatment of liver abscess. Such abscesses were not easily cleared out by aspirator, for they were largely traversed by trabeculæ, in which the matter was entangled. These could be broken down after free incision. Operation was often to be advised for the temporary relief of symptoms when cure was beyond hope.

The President regretted that physicians did not call in the surgeon earlier in these cases.

Dr. George Harley appealed for more facts and information. The data before the surgeon were very different to the data before the physician; the latter saw perhaps twenty cases to one seen by the former, and most of these twenty cases would be curable. He was surprised to find that any surgeon expected jaundice to be present when there was a stone in the gall bladder. He had thought that that heresy was extinct long ago. Jaundice from gall-stone occurred only when the stone was in the hepatic or common duct. The gall-bladder seemed to be an unnecessary luxury, for many animals, as the horse and the deer, had none, whereas all the higher animals except the birds had urinary bladders. The analogy suggested by Mr. Tait was not a true one. He said that he had evidence to show that hepatic cancer was often due to irritations caused by gall stones, and related a case in point.

Hydatids of the Liver.—Mr. Bruce Clarke, of London, read a paper on "Hydatids of the Liver," in which he advocated complete removal of the cyst-wall, although adhesions often caused difficulty in doing this when the cysts were situated on the periphery of the organ. It was better to operate early, before adhesions occurred. If complete removal were impossible a drain should be inserted, and kept in until the remains of the cyst-wall came away.

Actinomycosis of the Liver.—Mr. Frederick Eve, of London, speaking of actinomycosis of the liver, said that operations hitherto had all been unsuccessful. Diagnosis was often difficult, and the clumps of ray fungus might be searched for again and again in the discharge

from a sinus with negative results. He described cases of loculated abscess of the liver, presenting to the naked eye exactly the appearance of actinomycosis, which however, the microscope proved to be of different character. He would suggest that certain obscure tumors of the liver, which disappear after incision, might be nævoid. He had seen a case in the post-mortem room, supposed during life to be one of cancer, where the whole of the left lobe was replaced by a nævus. Such cases might end in spontaneous cure.

Mr. Mayo Robson said that he preferred the use of a large drainage-tube to suture of the duct, which it is very difficult to do securely. He had no experience of actinomycosis. He was certain that his cases were not nævi, on account of their cartilage-like hardness. He disapproved of removal of the gall-bladder as a routine practice, but it was necessary in some cases.

Surgical Treatment of Goitre.—Mr. Charters Symonds read a review of thirty-three cases in which this affection had been treated surgically. He said that all unilateral and median goitres were encapsuled tumors, and could be removed without interfering with the gland itself. He had always operated in the middle line. These tumors were generally (16 in 23) solid, and not amenable to treatment by injection. Solid tumors were softer than cysts, which were generally tense; if the case prove on incision to be one of cyst, this should be opened and dissected out; a solid tumor should be removed. The wall of a cyst was white and thick, especially if of long standing, while the wall of a solid tumor was purple and thin. Severe hemorrhage might happen in removing a solid growth. The plan he followed was to remove the tumor rapidly with the fingers, stop the bleeding by plugging or sponges, and then ligature the vessels at leisure. One of the growths operated on was bilateral, but was easily removed through a median incision. Such a tumor did not much resemble parenchymatous enlargement. He did not approve of injection of cysts with iodine or other substance. There was generally some solid growth, and suppuration was very apt to follow. When the tumor was solid throughout, injection caused too severe inflammation. In some cases, also, calcareous plates were encountered.

For parenchymatous goitre, resection of the isthmus was favorable only in soft, compressible, non-pulsating tumors. In one case of great dyspnœa isthmotomy did no good, but removal of one lobe was completely successful. In pulsating goitre, resecting of one lobe had an excellent effect. The nervous and other symptoms disappeared, the remaining lobe shrunk, and the exophthalmos had gone. He had removed as many as five encysted tumors from one lobe, leaving torn remains of gland-tissue. In nearly all cases primary union occurred, and healing was complete in about ten days.

Mr. Butlin, of London, had had good results from injection of perchloride of iron, which was meant to cause suppuration. The length of time required was the chief drawback to this treatment.

Mr. Lund, of Manchester, said that in a case of great dyspnœa he had divided the isthmus, and saw the displaced and twisted trachea at once right itself, with complete relief. Considerable wasting followed in both lobes. He had used iron and also iodine injections.

Mr. Bush, of Bristol, had seen severe bleeding follow tapping before injection, in three cases. One of these was nearly fatal. He was disappointed with the results of division of the isthmus. It did not always relieve the dyspnœa.

Mr. Mayo Robson had done a temporary tracheotomy as a preliminary to operation, where great dyspnœa existed. After the operation was performed he had sutured the tracheal wound, and could then irrigate the wound freely and dress it. He objected to injection, cases of which he had known to end fatally. In one case of tumor he had had to remove the entire lobe in order to check the bleeding. Section of the isthmus was, as in Mr. Symonds's case, not always enough, and might have to be supplemented by removal of a lobe. He preferred to ligature arteries first, then free the lobe, and lastly to divide the isthmus.

Intestinal Anastomosis.—Mr. Mayo Robson then read a paper on a new method of performing intestinal anastomosis. After speaking of Senn's method as a valuable and now recognized surgical procedure, he said that it had certain drawbacks. He claimed for his own method simplicity and ease in use, and that it did not leave large plates of bone to be absorbed. He used a tube of decalcified bone shaped like an ordinary cotton-reel. Two continuous sutures were used, the one through the margins of the openings of the two portions of gut, the other only through the serous coat at some distance from the edge. The sutures were first passed, the bone tube was next placed in position, and the sutures were tightened. In a case of gastro-enterostomy in which he had used this method, a post-mortem examination showed union to be perfect and the orifice smooth. He had performed a short circuiting operation by this method in seventeen and a half minutes.

Dr. G. H. Hume read notes of a case of enterostomy for cancer of the pylorus. The operation was quite successful. The patient afterward died of cancer. Senn's plates had disappeared, but the silk sutures still remained inside the gut. This was a possible danger.

Mr. Robson said that he hoped some day we should be able to do without plates or tubes. He had done so twice, but in one case stricture followed from the scar. He agreed with what Dr. Hume had said as to the objection to sutures that pierced the bowel-wall.

Third Day, Friday, July 29th.

Treatment of Spinal Abscess.—Mr. Watson Cheyne, of London, opened the discussion on this subject. He said that there was no greater proof of the progress in surgery due to Lister than the advances made in the last two years in the treatment of spinal abscess. He would divide the history of treatment into three periods: the pre-antiseptic, the early antiseptic, and the present antiseptic period. The results of treatment in the first period were decomposition after rupture or incision, sepsis and death, or hectic fever and lardaceous disease. Rest was the best treatment at that time, in the hope that absorption might take place. It was difficult to tell how often abscess was absorbed. Lannelongue held that this often happened, as shown by necropsy, but the speaker thought that the cheesy material which was taken to represent old abscess was often only degenerative tubercle. Late in the first period, aspiration or valvular incision gave better results. In the early antiseptic days the pathology of chronic abscess was thought to be the same as that of acute suppuration. Drainage with antiseptic precautions was therefore advocated. In 1888 Mr. Cheyne collected 58 cases thus treated, of which 49 remained aseptic; of these 38 were cured, 6 were still under treatment, and 5 died of tuberculosis.

The objections to this method were the length of time the treatment required, and the fact that the tuberculous material was left behind. Repeated aspiration before incision was then advocated, and the best time to open was also discussed. The general conclusion was that abscess should be opened as soon as possible, and as to situation, it was more important to keep away from sources of infection such as the perineum, than that the opening should be at the most dependent part.

At the present time it is known that the pathology of chronic abscess is not the same as that of acute. These abscesses are really tubercular tumors containing pus, and, therefore, simple drainage is not a radical method of dealing with them. The first attempt to deal with the tuberculous material was by applying an antiseptic to the walls of the abscess by the injection of iodoform in glycerine, or ether. Sinus generally resulted, and some

deaths were recorded. In one case under the care of Mr. Stanley Boyd, after injection of two drachms of a ten per cent. solution of carbolic acid, collapse, vomiting, carboluria, and death occurred. We now saw that the wall must be dealt with by scraping, and this method the speaker had used for the last four years. An incision should be made large enough to admit the finger, and the Volkemann or Barker spoon should be used; but where the peritoneum or large vessels formed part of the wall, rough sponges should be substituted for the spoon. Irrigation should be continued during the process. One or two ounces of iodoform emulsion might be injected and the wound closed by sutures.

In 24 cases of lumbar and psoas abscess thus treated, 13 healed by first intention, but 2 afterward returned with sinus. In 7 cases a small sinus remained in one part, of which 4 were operated upon a second time successfully. Nineteen cases out of the 24 were either cured at once or after a second operation. Three cases ended in death from pneumonia and other causes, and one child of two years died in collapse. In this case no iodoform was used. Post mortem nothing was found to account for death, which might perhaps have been due to fat embolism or injury to the sympathetic. The method was not absolutely safe, but the risk was worth running. Excision of the sac of the abscess entire was only possible when the laminæ were affected. When psoas abscess was confined to the abdomen it might be treated by lumbar incision, when in the groin by incision near the anterior superior iliac spine. In lumbar abscess the sac should be excised, the canal leading to the bones stretched, and the vertebræ scraped as far as possible. For irrigation he used a 1 in 10,000 solution of corrosive sublimate. It was difficult to decide whether iodoform injection was necessary or desirable. Unless iodoform would destroy the bacilli or stop their growth, it was of no use. Practically he found that, although some cases did well without it, iodoform was useful, and that the glycerine emulsion was better than ethereal solution, which was apt to cause sloughing.

Mr. C. B. Keetley, of London, thought that in carrying out the Listerian treatment it was not necessary to keep the patients in bed so long as was generally done. With a large, firm dressing applied on the principles advocated by the late Sampson Gamgee and a Sayre jacket, it was not necessary to keep a patient more than three or four weeks in bed. He thought that iodoform had probably nothing to do with death in Mr. Boyd's case, and referred to Mr. Cheyne's fatal case, where no iodoform was used.

As to sinuses and residual abscesses, he thought the last no reflection on the treatment. They might happen in any tubercular case long after operation, but were not serious. Spinal abscesses had a superficial and a deep portion. No thorough scraping was possible in the latter. He thought the lumbar incision was not of much use.

Mr. Noble Smith had had good results by incision and frequent syringing out with a one per cent. carbolic acid solution, without antiseptic dressing. He laid stress on the importance of absolute rest in these cases.

Mr. Charters Symonds would go so far as to say that no treatment was justifiable except incision and scraping. Rapidity of cure was one great advantage of the method, but the operation was a very tedious one. He was doubtful as to the value of iodoform.

Mr. Jordan Lloyd thought that the principles stated by Mr. Cheyne were the true ones. Of course we all presupposed fixation of the spine in these cases. Dissecting out a tubercular abscess was surprisingly easy, using the handle instead of the blade of the knife, but in spinal abscess this could not often be done, and even scraping of deeper parts was not always possible. He thought iodoform was distinctly useful.

Laminectomy.—In the absence of Mr. W. Arbuthnot Lane, his paper on the later results of laminectomy was summarized by Mr. Eve as secretary. Eleven cases were operated on, with one death immediately after operation and one from bleeding from a rectal polypus. Three other deaths occurred from causes unconnected with the operation.

He advised operation in all cases of pressure paralysis, if a short period of recumbency did not effect improvement. The operation was not dangerous, despite the enfeebled condition of the patients.

Mr. Cheyne said that he was surprised to hear from Mr. Keetley that he allowed his cases to get about so soon. He thought it not free from risk, as fixation was necessarily imperfect.

As to Mr. Noble Smith's remarks, there was little to be said. He must confess that he did not understand his method or his results. It was, of course, absurd to suppose that he (the speaker) did not use fixation. He always employed it very thoroughly, with double extension in most cases. Mr. Smith had admitted to him that he had had some fatal cases.

Enlarged Prostate.—Mr. Reginald Harrison read a paper on the "Restoration of the Lost Function of Micturition," and referred to a paper read by him at the meeting of the International Medical Congress at Copenhagen, on the treatment of enlargement of the prostate by stretching, incision, or partial excision, with drainage through the perineum.

The results of thirty-five cases were restoration of micturition in ten, besides the immediate relief of obstruction. By tunnelling the prostate in an old man of eighty-five, micturition was restored, the gland shrunk, and the patient remained well until his death, at the age of ninety. Restoration of micturition after prostatotomy or prostatectomy, was frequent even in patients who had been dependent on the catheter for years, and these cases, if left alone, were generally fatal. Operation was, however, not always called for, but only when relief by catheter was inadequate or impossible. In the earlier stages of enlargement, medical treatment was of more avail than was supposed. The long use of ergot, alone or combined with cantharides and nux vomica, often improved or restored the function of the bladder-muscle. The speaker maintained that the functions of the prostate were largely urinary, and not genital only. He related a case in which he divided the bar of prostatic tissue that blocked the passage. The cut ends retracted, showing that fibrous degeneration had taken place. This patient never used the catheter after the operation.

The President said that he thought the effect of operation was largely due to the rest given to the parts, which allowed inflammation to subside and its products to be absorbed, as well as to the actual removal of obstruction. Diet was most important in these cases.

Dr. Beverley read notes of a case of stone in a man aged seventy-eight. Two stones, weighing respectively three hundred and thirty-seven and two hundred and twenty-five grains, were removed by supra-pubic lithotomy, with a good recovery.

Mr. Charters Symonds thought, after hearing Mr. Harrison's paper, that perineal prostatectomy was much better than supra-pubic.

Dr. Hingston, of Montreal, said that after a full experience of supra-pubic and other operations, he concluded that the old lateral perineal operation was the best. Much larger stones could be removed by this method than the advocates of the supra-pubic method would have us believe. A stone weighing five ounces and five drachms had been safely removed through the perineum by the lateral incision. He thought that lithotrity should be the rule, except in very young children or very old men.

Ulcers of the Leg.—Dr Sidney Gramshaw read a paper on the treatment of chronic ulcers of the leg by a new method. In old varicose ulcers, Martin's rubber bandage was sometimes useful, but often failed, and it had the disadvantage of leaving the skin tender. The

speaker's method was to cleanse the ulcer by hot water gruel applied personally for half an hour, and to make the patient repeat this frequently for three days. He then applied a solution of one drachm of nitrate of silver in four ounces of flexible collodion. This must be kept in the dark, and painted over the surface of the ulcer, and for one-third of an inch beyond. A piece of lint cut to the shape of the ulcer, but a little larger, should then be smeared with an ointment consisting of one part of prepared chalk to seven of spermaceti ointment. The gruel should still be applied and the ointment renewed daily. Cure generally resulted in one month. He had only had one failure. In very bad cases it might be necessary to repeat the application of the caustic, or to use a stronger solution to begin with.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 10, 1892.

H. P. Loomis, M.D., President.

Old Gunshot Wound of the Hip.—Dr. Lewis A. Sayre presented a specimen from a case of the above.

The patient, General B——, came to him on January 6, 1864, stating that he had received a gunshot wound in the region of the hip, two years before, and that his case was considered hopeless. The patient was tall, thin, and anæmic, but remarkably well built. Examination showed just above Poupart's ligament on the left side, and just inside of the anterior superior spinous process of the ilium, an opening through which considerable pus was discharging. The probe not being long enough, a metallic flexible bougie was introduced into this sinus until it detected dead bone. Just then the end of the bougie sunk into a fissure in the ilium, and not being able to withdraw it easily, it was pushed forward until the end of the bougie could be felt below the posterior superior spine of the ilium, when it was cut down upon, and the end made to protrude. A large quantity of pus escaped from this new opening. There was a cicatrix near this wound, which the patient stated was from an old abscess which had dried up some months before. An eye was made in this protruding end of the bougie, and it was then threaded with oakum saturated with balsam of Peru, and then it was drawn through the entire canal, thus establishing free drainage. Although this was before the days of antiseptic surgery, this combination of oakum and balsam was really an excellent antiseptic dressing. It was the intention of the operator to pull fresh oakum through every day, cutting off the soiled portion, and he hoped after a while to be able to heal up the sinuses by a thorough scraping. On the following morning, Dr. Sayre was summoned in great haste to the patient, whom he found suffering great pain. Inquiry showed that the patient had been in such a hurry to get well that he had undertaken to carry out this treatment himself, by twisting on some fresh oakum. He had then forcibly pulled it through, and in doing so, had broken off large pieces of bone, one of which was pressing into the buttock. By a star-shaped incision, and the use of strong forceps, several large pieces of the ilium were removed, the largest of which was an irregular triangle, one inch long, and measuring more than half an inch at its base. This piece was from the wing of the ilium, and showed the external and internal plates, but was, like the other, entirely devoid of periosteum. That evening, the patient left the city for Washington. He returned on September 4, 1865, and called at intervals of a few months, in order to have the drainage kept free. The patient would not consent to giving up his work long enough to enable the parts to be thoroughly curetted. In June, 1874, he came from Chicago in very bad health, as a result of obstruction of the drainage. The wound was enlarged, and a number of small pieces of bone removed, which so straightened the canal as to admit of passing a large perforated drainage tube. For the last two or three years, the drainage had been better and the discharge scanty. He took cold quite recently, and died on January 29, 1892, in the sixtieth year of his age. By the kindness of the attending physicians, Drs. Shrady and Carleton, he had been invited to be present at the autopsy, and the family had permitted the removal of the specimen, which he now presented to the Society before sending it to the Army Medical Museum. On opening the abdomen some ounces of embalming fluid escaped, but there was no effusion or evidence of recent peritoneal inflammation. The sigmoid flexure of the bowel was firmly united to the peritoneum in the iliac fossa by old adhesions. An incision was made through the left lumbar region at the sacro-iliac junction, and the limb entirely removed with part of the intestine attached, and with the india rubber tubes still in the sinuses. On cutting open the intestine, it was found that there had never been any injury to its internal or mucous coat, and that the whole mass was firmly adherent to the ilium of the place where the ball first entered that bone. All the sinuses were healthy except about one inch of their course through the bone, and this diseased tissue could have been easily removed by scraping, and the wound perfectly closed without danger. The entire portion of the ilium removed at his first operation had been more than replaced by perfectly healthy bone, which was nearly two inches in thickness in many places.

Dr. Sayre then read two letters, one from a postmaster in Ohio, describing a very similar case, and the other, from Dr. D. P. Chamberlain, the army surgeon who saw General Barnum about twenty minutes after he was shot. He wrote that from a hasty examination, made at the time, he stated that he did not believe there was any immediate danger, notwithstanding the location of the wound, and he based this opinion on the fact that the wounded officer lacked the shock and the peculiar leaden countenance indicative of intestinal perforation. Dr. Sayre said he wished to call particular attention to this statement, as he believed it contained an important aid to a correct prognosis in this class of cases.

Dysenteric Ulcers.—Dr. C. G. Currier presented specimens that had been removed from a patient fifty-eight years of age, and were chiefly interesting on account of the number of these ulcers, which, together with the capillary hemorrhages, were found scattered over the colon. The spleen from this patient was also interesting, as at first glance it might be taken for a tuberculous spleen, but closer inspection showed that there was only a thickening of the capsule from a perisplenitis. The heart showed hypertrophy, and the aorta was the seat of atheromatous changes.

A Needle in the Abdominal Cavity.—Dr. George P. Biggs presented an interesting specimen of a foreign body in the abdominal cavity. It was removed from a woman sixty years of age, who died of pulmonary tuberculosis without any symptoms bearing upon the foreign body. Aside from the lesions of the tuberculosis, the autopsy showed nothing of interest except a needle, located transversely in Douglas's cul-de sac. It was 6½ ctm. in length, and 1½ mm. in diameter, and was entirely covered by fibrous adhesions, which practically shut it off from the general abdominal cavity. Only a part of the eye of the needle was left. There was no evidence of any operation having been performed, and there was no uterine disease present. Whether the needle had found its way to this locality from the intestinal canal, or whether it might have been the result of an attempt at abortion, he was unable to say.

Diabetes.—Dr. J. S. Thacher exhibited a specimen illustrating a peculiar condition of the blood occasionally associated with diabetes. One or two writers had spoken of this as not being very uncommon, but he had never met with it before, and in a series of thirty-seven cases reported at the London Hospital it was not found, and in forty-three cases at Guy's Hospital it was only noted twice. Some observers have thought it was produced by

a sudden transformation, shortly before death, of the excess of sugar into fat, while others have believed it to be caused by acetone in the urine. Still others have claimed that it is not fat, and that the result follows mixing acetone with urine; but the weight of evidence is in favor of its being fat. A microscopical examination of the blood just presented showed it to be crowded with minute granules, smaller than the smallest micrococci, but on mixing the blood with ether an emulsion was obtained, which presented under the microscope an appearance similar to that of milk. He had also extracted this substance from the blood with ether, and after the evaporation of the ether there was a greasy residue. It had been suggested that the attacks of coma with impeded respiration, such as we occasionally notice in connection with diabetes, are due to the formation of fat emboli in the lungs, but the evidence seems to point to a different etiology.

This specimen of blood was removed from a girl about fifteen years of age, in the service of Dr. Beverley Robinson at St. Luke's Hospital. About four or five months before her death she began to lose flesh and strength, and to suffer from great thirst. During the three months she was in the hospital the urine contained no albumin, and the daily average of sugar was from four to six per cent., or from two hundred to two hundred and seventy ounces. She gained in weight slightly immediately after admission, but afterward lost flesh steadily. The day before her death she was up and around the ward; about ten hours before death she was found to be cold, and suffering from labored breathing, and three hours later, after a dose of morphine, she was found asleep, with a pulse of 130, and respirations 16 and very deep. About six hours before death she was seized with a tonic spasm, which lasted for about ten minutes, and was succeeded by coma which continued until her death. All the vessels in which any blood was found contained blood of white color, or of the pinkish hue shown in the specimen. In the heart there were some reddish coagula, and a quantity of blood looking like coagulated milk. The occurrence of dyspnœa is interesting in connection with this fatty condition of the blood.

Rupture of the Middle Meningeal Artery.—Dr. A. T. Weston presented a portion of dura mater showing rupture of the middle meningeal artery. The man from whom the specimen was taken was about thirty-nine years of age. About 12 o'clock on the preceding day he had received a blow on the head from an Indian club. He went home, and, feeling sick, went to bed, and, as it was thought, went to sleep. About 3 P.M., when his children returned from school, they found that he could not be awakened. He was then found to be completely comatose, and about two hours later he died in the hospital.

There was no ecchymosis externally, but on removing the calvarium, a large clot was found separating the dura mater from the skull, which measured four inches anteroposteriorly, and about one and a half inch in its thickest part. There was also a linear fracture, about three and a half inches long, extending perpendicularly about one and a half inches in front of the ear. The clot pressed on the brain sufficiently to cause extreme flattening of the convolutions of the left hemisphere. There was also a slight contusion on the right side of the tempero-sphenoidal lobe, from contre-coup. There was no other ruptured vessel. He had seen quite a number of cases of this kind, and in the majority of them there was no fracture, and no injury to the brain except the compression. He thought something might have been done surgically for this case, if the treatment could have been instituted sufficiently early.

Dr. L. A. Sayre concurred in the opinion that if the diagnosis had been made sufficiently early it would have been a proper case for trephining and removal of the blood-clot.

Weigert's Recent Staining for the Nervous System.—Dr. Joseph Collins presented microscopical specimens of the above. According to this method, which he had already described in an article in the New York Medical Record, last October, nerve-fibres were shown with unusual distinctness, and the contrast between the ganglionic cells and their fibres was much better than by Weigert's older method, and the time occupied in preparing the specimens is much less. The results are also more certain if proper precautions be taken in the staining.

The tissue is hardened in Muller's fluid, and treated in the usual way with ninety-five per cent. alcohol, and then immersed for an equal time in absolute alcohol. It is next treated for about the same length of time with thin celluloidin, and is then placed on a cork and immersed for twenty-four hours more in thicker celluloidin, after which comes the "coppering." The tissues are floated for twenty-hours in a mixture of equal parts of a ten per cent. solution of tartrated soda, and a cold saturated solution of acetate of copper, which is kept in an incubator at a temperature of 38° C. for about twenty-four hours. They are then transferred to a mixture of equal parts of the acetate of copper solution and distilled water, and are allowed to remain in this for another twenty-four hours, after which they are transferred to eighty per cent. alcohol until ready for sectioning. The sections ought to be quite thin, and large pieces require to be treated for twenty-four hours more, at the same temperature, in a mixture of equal parts of water and a saturated solution of cupric acetate. The staining fluid consists of two solutions, which should be kept in separate bottles, and freshly mixed each time. The first solution is the ordinary alcohol hæmatoxylin solution (1 gramme hæmotoxylin to 10 c.c. of alcohol), and the second is a mixture composed of 7 c.c. of a saturated solution of lithium carbonicum in water, and 93 c.c. of distilled water. As ordinarily used, five parts of the first solution are mixed with forty-five parts of the last mixture, and the sections are allowed to remain in this fluid for from four to twenty-four hours, or even for a longer period, when it will be found that differentiation has taken place, thus doing away with the older and much more tedious process of differentiation. The sections are washed in distilled water, dehydrated in ninety per cent. acohol, and clarified in anilin xylol (2 to 1), after which they may be mounted in balsam or in dammar. The balsam must be diluted with xylol and not with chloroform, as the latter would remove the stain from the fibres. If the specimens are not sufficiently decolorized, wash two or three times with water after coming out of the hæmatoxylin solution, or immerse in a half per cent. solution of acetic acid for a very short time.

Dr. Collins exhibited a specimen from the medulla, and also one of the cortex of the brain of Nordcross, the bomb-thrower. This specimen was taken from the frontal convolutions, which appeared at the autopsy to be normal. Under the microscope, the specimen shows an extraordinary fineness of the protoplasmic axis cylinders.

Fibroid Tumor.—The President presented a specimen showing a fibroid tumor complicating pregnancy. The uterus contained a fœtus of about two and a half months, and a large fibroid tumor involved the right uterine wall and the anterior portion of the uterus. The patient was twenty-eight years of age, and was perfectly well up to two and a half months before admission, when the menses ceased and she began to suffer from reflex disturbances, especially from pain in the lower portion of the abdomen. At times she had what she called "a greenish discharge." On admission, examination showed a mass to the right of the uterus. It was decided that the mass was not a fibroid, but an extra-uterine pregnancy, on account of the reflex disturbance and many of the symptoms of pregnancy which were present. Laparotomy was performed by Dr. Barrows, and as soon as the mistake was discovered, the uterus was replaced and morphia given to stop the uterine contractions, but within forty-eight hours the patient died. The cause of death was apparently shock, as there was nothing about the opera-

tion-wound to suggest any other cause. The specimen illustrated the difficulties in diagnosis presented by this class of cases.

Sudden Death Due to Fatty Degeneration and Dilatation of the Heart.—The President also presented specimens from the above case. On the previous evening the man was walking along the street in apparent health, when suddenly he fell dead. At the autopsy, no cerebral hemorrhage was found, and no pathological changes except in the heart and, secondarily, in the kidneys. The heart was excessively dilated, and microscopical examination showed that the cardiac walls were the seat of extensive fatty degeneration, hardly any of the muscular fibres having escaped this degenerative change. There were no arterial changes and no blood-clots in the heart. The kidneys showed moderate parenchymatous nephritis. The case was interesting as affording an explanation of many cases of sudden death.

The Society then went into executive session.

Correspondence.

YELLOW FEVER AND THE NEGRO.

To the Editor of the Medical Record.

Sir: In a recent number of the Medical Record you stated that, although the African negro is believed by many to possess immunity from yellow fever, the question cannot be considered as settled. Allow me to call your attention to an extract from a letter of C. Creighton, which appeared in *Nature*, June 30th, and which is quoted in *Science*, July 15th: "This point (the immunity of the Ethiopian from yellow fever), interesting to anthropologists, is raised anew by a writer on the history of epidemics (*Nature*, June 16th), who asks whether the alleged protection is supported by all recent authorities. Recent authorities are not so well placed for judging of this matter as the earlier; for the reason that immunity is not alleged except for the African negro of pure blood or unchanged racial characters, and that these conditions of the problem have been much less frequently satisfied in the yellow fever harbors of the western hemisphere since the African slave trade ceased. However, there was a good opportunity in 1866, during the disastrous yellow fever among the French troops of the Mexican expedition when they lay at Vera Cruz. Among them was a regiment of Nubians, who had been enlisted for the expedition by permission of the Khedive: that regiment had not a single case of yellow fever all through the epidemic. The African negro regiment brought over from the French colonies of Martinique and Guadeloupe had two or three cases, with, I think, one death. The rest of the troops, including Frenchmen, Arabs from Algeria, native Mexicans, and Creoles, had no immunity whatever, but, on the other hand, a most disastrous fatality. The medical officers of the French service have recorded the facts principally in the *Archives de Médecine Navale*, their conclusion as to racial immunity being the same that has passed current among the earlier authorities as a truth of high general value (admitting, of course, of exceptions in special circumstances), and a truth that has never, so far as I know, been formally controverted by anyone, although other points concerning yellow fever have been the subject of as obstinate controversy as those touching smallpox itself. The experiences of the French at Gorée, a town with ten times as many negroes as whites, exactly confirmed those of Vera Cruz in the same year (*Archives de Médecine Navale*, ix., 343). The immunity of the African negro from yellow fever has become a paragraph in some anthropological text-books. It is from the anthropologists, and not from medical authorities, that Darwin cites the fact in his "Descent of Man," adding an original theory of the immunity which he was unable to establish after much inquiry. His theory, I need hardly say, was not that "negroes in infancy may have passed through some disease too slight to be recognized as yellow fever"—whatever that may mean—"but which seems to confer immunity." The theory, however, is another story, or "another volume," as the writer just cited is pleased to suggest; and as for the historical fact of immunity, no one denies it, unless it be Dr. Pye Smith in his recent Lumleian lectures (*Lancet*, April 23, 1892, p. 901), who gives no reasons. It is unfortunate that the anthropologists (Darwin among them) should have introduced one element of dubiety in placing mulattoes on the same footing, in respect of immunity, as negroes of pure descent, and another in mixing up malarial or climatic fevers with yellow fever."

This author evidently inclines toward a positive assertion of the immunity. I have, myself, to offer some facts, which I think I might call collateral, and which, in an indirect way, speak rather for Creighton's affirmation than for your own hesitancy of belief. You are aware, without doubt, that the Japanese have, at least until these very latest times, enjoyed two immunities, which undoubtedly belong to the negro race: the immunities from scarlet fever and locomotor ataxia. Some say that the thin edge of the former disease is beginning to penetrate into the race. But the immunity during the past is quite sufficient for my purpose of argumentation. The Japanese have been in the past closely allied to the negroid races; the black element is now quite fusioned with the other elements of the race. Nothing is more probable than that the two Japanese immunities which I have mentioned are a transmission from that partially parent stock. The Japanese have had as yet no experience with yellow fever. But that may possibly be explained by their never being really exposed to it. It will be interesting to see whether the Japanese immigrants, now, it is said, flocking to Mexico, will there, under less favorable circumstances, remain untouched by the fever.

The Japanese have, as I said, a negroid inheritance. The negro is probably the most ancient of human races. The most ancient pathological origins can be traced back to it: leprosy, syphilis, tuberculosis, etc. Is it not likely that, in this ancient race, some pathological tendencies have run their course, some diseases have exhausted themselves, and that immunities have thus been attained which the younger European white race does not yet possess?

Creighton's conclusion, that it is unfortunate that an element of doubt should have been introduced into the matter by placing mulattoes on the same footing, in respect of immunity, as negroes of pure descent, corroborates what I said in my recent discussion with Dr. Stillé, in the Medical Record, that the introduction of Caucasian blood would be followed by the transmission of susceptibility to scarlet fever, to the Japanese race.

Very sincerely,

Albert S. Ashmead, M.D.

4 King Street, New York.

A RETRACTOR FOR AMPUTATIONS.

To the Editor of the Medical Record.

Sir: Under the caption of "New Instruments" I notice, in the Medical Record of July 30th, an article by Dr. E. J. Meyer, of Buffalo, N. Y., describing his retractor for amputations. I hereby wish to congratulate Dr. Meyer on the most efficient retractor he devised, and yet beg to object to the words "a new instrument," as given in the description of same.

Ever since 1888, Professor F. O. Guermonprez, of Lille, France, of whom it was my good fortune to be the "interne" for more than three years, uses a metallic retractor similar to the one figured by Dr. Meyer, and made of two zinc plates which, when in use, partly overlap and receive the bone or bones to be divided within a lateral recess, thus insuring all the advantages claimed for the instrument previously described.

The fact, however, that at such a distance two wide-awake and practical surgeons have each for himself hit

on the same idea, goes to prove that a real need has been filled, and that the metallic retractor has undoubtedly come to stay.

THE ANCIENT HISTORY OF A NEW EAR INSTRUMENT.

To the Editor of the Medical Record.

Sir: In the Medical Record of May 28, 1892, Dr. Frank Allport has an article on "Some New Ear Instruments, with Remarks on the Treatment of Chronic Purulent Inflammation of the Middle Ear." In this article he calls attention to a "modification of a recent instrument and to two new ones." One of these new instruments he calls a "smooth ear-curette."

To me this curette was by no means new, as I have been using it for over eleven years. It has been kept in stock by several Philadelphia instrument makers (Kolbe, Lentz, Gemrig) for a number of years. So far as I know, the instrument was devised by Dr. George Strawbridge, of this city, many years ago. I remember that in his lectures on the ear at the University of Pennsylvania, he always showed this instrument to the class, and specially emphasized its value It is now within a few months of thirteen years since I first heard him speak of this curette and demonstrate its value. I believe he named it the "Blunt Ear-curette."

Of the curette's usefulness in many cases there can be no doubt. Anyone who is engaged in doing much ear work will, if he has used it, testify to its value. In the hands of those who are inexperienced in this line of work it might prove harmful, but probably less so than any other metal instrument used in the same way.

Being sorry that I have been compelled to prove a new instrument an old one, I am,

Yours respectfully,

Louis J. Lautenbach, M.D.

1723 Walnut Street, Philadelphia, Pa.

THE MICROBICIDAL ACTION OF TOBACCO-SMOKE.

To the Editor of the Medical Record.

Sir: In your number for July 2d, page 10, is a reference to the experiments of Tassinari, to ascertain the influence of tobacco-smoke upon the growth of bacteria. Other medical and scientific journals have also contained such accounts, but nothing has been said of the earlier work of Dr. W. D. Miller, an American dentist practising in Berlin, holding the position of Professor in the Dental Institute of the University of Berlin, and I believe the only foreigner ever appointed to a Royal professorship in Germany.

In an article upon "Fermentation in the Human Mouth," published in *The Independent Practitioner* (a monthly dental journal then published in Buffalo, N. Y.) for June, 1884, pages 284 and 285, Professor Miller, after detailing experiments with the juice of tobacco upon the bacteria of the oral cavity, goes on to say:

"Yet more remarkable, however, was the action of tobacco-smoke upon the fungi; the smoke from the first third or last quarter of a colorado claro cigar being found amply sufficient to sterilize ten cubic centimetres of a beef-extract-sugar solution, previously richly infected with caries fungus. . . .

"In consideration of the strong antiseptic power of tobacco-smoke, we might be inclined to infer that tobacco-smokers should never suffer from caries of the teeth; it is evident, however, that there are many points in the dental arch to which the smoke never penetrates."

A cut of the apparatus used in the experiments, with a full description of the process, accompanies the text. In the first volume of "The American System of Dentistry" (Lea Brothers & Co., 1886), the article, with the illustrations, is reproduced. The experiments of Miller antedate those of Tassinari by a considerable period, and are quite as conclusive.

I am very truly yours,

W. C Barrett, D.D.S., M.D.

208 Franklin Street, Buffalo, N. Y.,
August 17, 1892.

New Instruments.

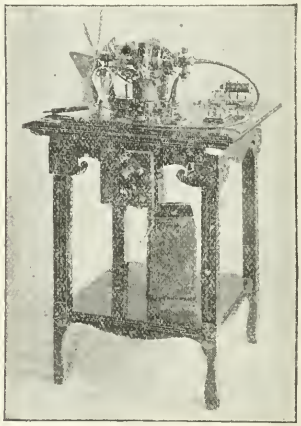
AN ELECTRIC MACHINE FOR THE PRODUCTION OF ALL KINDS OF ELECTRICITY FOR MEDICAL PURPOSES FROM A SINGLE STORAGE BATTERY.[1]

By ROBERT L. WATKINS, M.D.,

New York.

I have believed for a long time that electricity, for all varieties of medical use, could be generated from one storage battery. The machine which I now take pleasure in presenting before you, constructed for me during the last year, is the result of experimentation for some time past, to meet this need I have long felt. I have found it to work with satisfaction in many cases, and especially in diseases where the galvanic current has formerly answered.

Without describing the apparatus in detail, going into technicalities, or giving electrical measurements, I will,



for the sake of brevity, in as few words as possible, outline the machine and demonstrate its simplicity and practicability; for it is not complicated or liable to get out of order. The machine is small, well made, and constructed by reliable and skilful workmen. This transformer is composed of a motor and an electric generator combined. Its weight is about thirty pounds. The electricity is taken from one storage-cell weighing about fifteen pounds. The current which can be taken off from the terminals of this transformer is about one hundred volts, and the current given can vary from 150 milliampères down to zero. It is thus seen that a current equivalent to that from 60 Leclanche cells is easily obtained. This electro-motive force can be varied according to the use or muscular contraction required, by means of a small regulator on the motor. The size of the storage-battery can vary according to the kind and amount of work to be done; and this in turn can be charged from the street current, from an electric light station, or by means of primary batteries, which may, if used, be kept constantly in circuit. This will keep the storage battery in good condition.

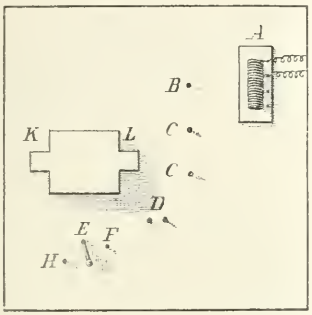
[1] Read before the New York County Medical Society, April 25, 1892.

Before demonstrating the working of the machine, I will describe the cabinet attachments :

1. Here are two binding posts connected direct from the storage-cell for use in cauterization and electrolysis. On account of the latter use and the heavy cautery work, two other storage-cells are in my cabinet at home ; so I can obtain six volts with, of course, a larger ampèrage.

2. I have an induction coil for the faradic connected direct to the storage cell.

3. I use a Vetter's current controller for a variety of purposes.



Top View (24 × 24 inches). *A*, Faradic coil ; *B*, *C*, connections for light ; *C*, ... direct or galvanic current ; *E*, switch, either for light when on *H*, or for direct current when on *F* ; *K*, motor end, and *L*, generator end of machine ; *D*, cautery posts.

Demonstration.—1. I will switch on the faradic, the buzzing of which is so familiar to you all as to require no further demonstration.

2. I now attach the sponges to the electrodes and take the current direct, which current corresponds with the galvanic. You perceive by means of this current-controller on the motor I can vary the strength of the electricity according to the contraction required.

3. I now attach my cautery of two volts, which is sufficient, if properly arranged, for most any cautery work.

4. I now slow up and attach the fan sometimes used in the sick-room, to keep the air in circulation. This fan is now revolving at the rate of 1,800 revolutions per minute, and the machine generating an electro-motive of over one hundred volts.

5. I now attach the drill. Its use in nose and throat work you are all familiar with.

6. Now, gentlemen, for transillumination and for examining cavities, I introduce an electric light of 15 volts, and thus do away with the low voltage lamp for one of high voltage, which produces little or no heat ; for, as you are aware, one of low voltage heats up so quickly as often to prevent its use. Lamps of any size can thus be used with this machine. The machine is now running at the rate of 1,800 revolutions and developing 150 volts. To prove the voltage developed, as near as possible, I will slow down the electro-motive force and connect a 100-volt eight-candle-power Edison lamp. You will now observe that all appliances attached to the machine are running simultaneously. If more power is wanted for any purpose, it can readily be obtained by introducing another storage-battery in series, and thus having 4 volts in the primary circuit the power will be doubled ; I will then obtain 200 volts or more, $\frac{1}{2}$ an ampère, $\frac{1}{6}$ of a horse-power, and 4,000 revolutions per minute.

Several of these machines have been made by electrical engineers for me during the past two years before one was obtained which worked successfully, and for that I am indebted to Mr. Nikola Tesla.

320 West 145th Street.

Jenner and Japan.—The physicians of Japan are taking steps to celebrate the Jenner centenary by the erection of a statue to that "medical benefactor of mankind."

LAMBLIN ABDOMINAL NEEDLE.

By J. W. SMITH, M.D.,
ST. LOUIS, MO.

This needle needs no manipulation other than its thrust through the tissue and its withdrawal after it is threaded, as it is self-adjusting. It is provided at the posterior arch of the eye with a little fly, which is caught by the tissue as the needle passes through, thereby opening the eye to receive the ligature. It is then threaded and withdrawn. In so doing the little fly is caught by the tissue and completely closed over the ligature, by which it not only prevents the ligature from slipping out of the eye of the needle, but also acts as a guard for the tissue from the spear point. When flaps or wounds to be stitched are obese, thick, or heavy, it is very difficult, with the old-style needle and needle-holder, to pass the needle through both sides at the same time, requiring the adjusting and readjusting of the needle-holder, consequently considerable time is wasted and unnecessary pulling, stretching, and handling of the tissues, which are not to be encouraged, especially in dealing with peritoneal membrane.

In abdominal stitching the needle should be held so as to allow the index-finger to rest within a half or three-quarters of an inch of the needle point, so as to guard its depth and course, in order to prevent the careless wounding of the intestines or other tissues. With an experienced assistant an ordinary laparotomy wound may be stitched and tied in two or three minutes after the peritoneal tissue has been caught and held by the forceps. The more tedious and serious the operation has been, the more important is the time saved at this stage of the operation, for it is now the patient has reached the climax and very likely is entering the state of shock from the sudden removal of pressure caused by large tumors, loss of blood, or long-continued anæsthesia, etc.

I have also used this needle in stitching scalp wounds, and in sewing up flaps after amputations ; in fact, it will be found advantageous in most all stitching of the soft parts.

The Lamblin needle is an all-metal aseptic instrument, needle and bar made of steel and about five inches long, with fluted metal handle hermetically soldered to needle-bar ; the handle is four inches long, thus making the entire instrument nine inches in length.

I am indebted to Messrs. A. S. Aloe & Co., of this city, for the perfect model of this instrument, being manufactured from the original pattern of Collin et Cie, Paris, as made for Professor Lamblin, the original model being imported by the above firm, and first introduced into this country about one year ago.

The Medical Missionary.—A Hindoo, jealous of the encroachments of Western civilization on his traditional beliefs, when asked, "Which of all the methods of that civilization do you fear the most?" naturally enough evaded the question, remarking, "Why should I put weapons in the hands of an enemy?" At last he said, "We do not greatly fear the missionary schools, for we need not send our children. Nor do we fear their books, for we need not read them ; nor their preaching, for we need not listen to it. But we dread the doctors and the women. The doctors are winning our hearts and the women our homes ; and when our hearts and homes are won, what is there left of us?" It is, in truth, with the advent of the medical man and the trained nurse that progress has been made in the reclamation of the backward Oriental, and the annals of missionary enterprise would lose half, and more than half, of their practical interest if these two factors of their work were omitted from the record.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 20, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	49	10
Scarlet fever	34	2
Cerebro-spinal meningitis	0	2
Measles	85	6
Diphtheria	49	13
Small-pox	6	1
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

The Lessened Vitality of Females at the Time of Puberty and Adolescence is a striking fact, according to Sir James Crichton Brown. Throughout life, in every quinquennium, the mortality of males from small-pox exceeds that of females, and that in a very marked degree, except in one quinquennium from the tenth to the fourteenth year, when the female exceeds the male mortality, being again but very slightly behind it in the succeeding quinquennium from the fifteenth to the nineteenth year. At all ages the male death rate from enteric fever exceeds that of females, but the female mortality is very considerably higher from the third to the twentieth year of life. In infancy and also in old age, the male mortality from diarrhœa and dysentery exceeds the female mortality, but in the child-bearing period, from fifteen to forty-five years of age, the mortality is distinctly higher among females. And even more striking in this connection are the statistics of phthisis than those of zymotic diseases. Phthisis is more fatal to males than females under five years of age; but then a change takes place, and from five to ten it is much more fatal to females than to males; while from ten to fifteen it is more than twice as fatal to females as to males. From fifteen to twenty phthisis is still much more fatal to females than to males; from twenty to twenty-five the mortality from it is exactly equal in the two sexes, and from twenty-five to thirty, and at all subsequent ages, the mortality from it is much greater among males than among females. Dr. Brown is inclined to attribute this to over-pressure in education; but surely there are many other factors more important in lowering the vitality of young women.

Chlorosis Treated by Sulphur.—Dr. Schulz calls attention to the value of sulphur in certain cases of anæmia and to the excellent results obtained by the use of sulphur waters in malarial cachexia. He draws the following conclusions: 1. In cases of pure chlorosis in which iron proves inefficient, the general condition is decidedly improved by sulphur. 2. After the administration of sulphur has gone on for some time, treatment with iron can be commenced and continued with success. 3. In cases of chlorosis complicated with catarrhal and inflammatory conditions of the digestive track, sulphur is contra-indicated.—*Berlin klin. Wochens.*, No. 13, 1892.

A Frank Consultant.—Sir William Gull may be taken as a type of the candid consulting physician. His remarks to his professional brother, who had called him in, were sometimes almost as unreserved as if he were thinking aloud. In a recent memorial notice of Dr. Gull, in *Guy's Hospital Reports*, we find mention of the following instances bearing on this subject: He once met a physician in a case of rheumatism in which Dr. Gull recognized a pericardial friction sound. Nothing was said to the family about this newly discovered element in the case; the general treatment was approved and the two medical men left together. The physician in charge expressed his thanks to the other that he had not disclosed the "dreadful oversight," and added: "I cannot think how I can possibly have failed to detect the pericarditis." "Never mind," said Gull, "it is just as well, for, if you had detected it, perhaps you might have treated it." To a family practitioner who had much to say about his patient's constitution and peculiarities, Gull would say: "How can you understand anything about this man's 'constitution,' when you have never made an examination of his urine?"—*New York Medical Journal.*

The Therapeutic Uses of Iron.—The tonic and hæmatinic properties of iron were well known to the ancients. The old way of administering this metal was very curious. The metal being very much used in the preparation of weapons of warfare, and Mars being the god of war, Mars became the patron of iron; and very frequently in old books we read of the "martial preparations," by which is meant preparations of iron, and the mode of administering them was to put a sword into a water-trough and allow it to lie there and rust, and to let the people drink of the water. Of course, it was a very mild chalybeate water that could be got in this way. But still, very mild preparations of iron, if continued for a long period of time, will produce a very marked effect; and distinct results were obtained in ancient times from this very mild way of giving iron.—*Lancet.*

Oatmeal Pyrosis.—The author of the *Asclepiad*, Dr. Benjamin W. Richardson, says, in a recent number of that publication: "An obstinate case of pyrosis came under my care some years ago, and resisted all forms of medical treatment. The dietary of this patient, an orderly and temperate man, seemed to call for little supervision; in fact, I never remember to have had under my care anyone who was simpler or more methodical in the way of feeding and drinking. I recommended him to leave off tea, and he obeyed, but with no beneficial result. Coffee was withdrawn, with no better result. The patient was an abstainer from alcohol and did not smoke, so reforms were not called for in those directions. For a time he left me and consulted another physician—I believe more than one—but after a few months he returned, complaining of the continuance of the symptom that so oppressed him. He really suffered acutely. Each morning, between breakfast-time and luncheon-time, the water-brash came on. The quantity of food ejected from his stomach was considerable, and the ejection was preceded by a sense of sinking at the heart and faintness which sometimes alarmed him. By the free discharge of the fluid from the stomach he was invariably relieved, and rarely had any return of symptoms until the following day. The story of the repetition of the attack, always at the same or about the same hour, was so peculiar and so often repeated that I could not fail at last to attribute it to something taken at breakfast; and finally I began to suspect that a dish of oatmeal porridge might be the enemy. He had taken this for breakfast for many years, and had never thought it injurious, and when I named my suspicion he was incredulous. However, he took the advice to leave off oatmeal 'on trial,' and from the day of leaving it off had no return of his symptoms. Six months later he ventured the oatmeal diet again, and in a week was as bad as ever. Once more he left it off, and once more was completely cured. This was observation on a patient; but, for experiment's sake, I tried the effect of oatmeal diet on myself, with the result of setting up in a few weeks as decided an attack of pyrosis as could be observed or felt. In my own case I found that barley-water, repeated for a time, produced the same result. After making these observations I continued to inquire, in all instances of pyrosis I have since met with, whether oatmeal formed a part of the dietary of those affected; and I have found so many corroborative experiences that I am led to think there is no more frequent cause of pyrosis than oatmeal or a similar fermentative food."

UPON A POSSIBLE ELECTRIC POLARITY OF METABOLISM, AND ITS RELATIONS TO ELECTRO-THERAPEUTICS AND ELECTRO-PHYSIOLOGY.

A Suggested Basis and Guide for Medical Treatment by Electrical Energy.

By WILLIAM JAMES MORTON, M.D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM AND ELECTRO-THERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING NEUROLOGIST TO RANDALL'S ISLAND HOSPITALS.

I. **Electro-Therapeutics.**—Upon initiating, at the Post-Graduate Medical School and Hospital, a clinic for the treatment of diseases by electricity, I was, at the outset, in face of the great variety of diseases to be treated, met by a difficulty that had long confronted me, and that doubtless has opposed itself to the efforts of most physicians in the attempt to apply electrical energy to medical use. That difficulty was to decide upon some rational method of applying the energy to combat disease.

I do not now refer to electro-surgical procedures, like galvano-cautery, where the heating effects of the current is availed of, nor to galvano-caustics, where the local chemical action of electrolytic products is relied upon, but rather to the general applications of electricity in medicine. In these the practitioner finds in his power for use a greater number of therapeutic effects than cluster around any other curative agency. For the sake of simplicity, the galvanic current only is referred to. From a physiological point of view, he may rest upon the certain basis of the contractile effects of electric currents upon animal protoplasm, or upon vaso-motor effects, and upon the phenomena of electrotonus, or may confine his treatments to ascending and descending currents; or he may turn to chemico-physical effects, and may base his treatments upon electrolysis, polar, and intra-polar, and upon cataphoresis; or, finally, he may turn to general medical literature and adopt a clinical basis, as an example of which I quote a list of purposes which electricity may serve, as given by a recent writer of note, viz.: Sedative, stimulant, counter-irritant, and vesicant, muscle contraction, antispasmodic, tonic, promoter of development, absorbent, chemical cautery, coagulator, electrolytic, hæmostatic, promoter of hemorrhage, decongestor, and as a medicator. The result of this embarrassment of riches, so to speak, in electro-therapeutics is a lack of unanimity of opinion as to the employment of any given method. As regards the choice of one pole or the other, there exists but one fixed procedure, based upon the physiological statement that the positive pole is sedative, and the negative stimulating to nerves.

Again, from the point of view mentioned, as well as from many others, electro-therapeutics, like all other branches of therapeutics, is far from being an exact science. We know neither the processes of disease, on the one hand, nor the mode of action of remedies on the other. We are treating the unknown by the aid of the unknown; we cannot define life, nor that perversion of life processes which we call disease. We cannot define electricity, nor do we know its mode of action upon the tissues, except in a secondary sense, as a liberator of destroying chemicals or in a mechanical or chemico-mechanical sense, as in cataphoresis, or in a physiological sense, as an excitor of the irritability of nerve and muscle. But, though our knowledge of the action of drugs and of electricity is imperfect, we are not relieved from the duty, as physicians, of continuous endeavor to secure further knowledge. That electricity, that drugs possess definite and powerful actions for good in disease admits of no doubt. With the fact itself we are confronted, and it is this we must attempt to solve. We are in the midst of the studies of the normal and morbid processes of disease, from the standpoint of physiology, particularly chemico-physiology; the animal cell, so long the subject of morphological investigation, is now being subjected to a searching chemico-physiological scrutiny. The story of its protoplasmic life, as it is being unravelled, throws daily light upon disease and upon the mode of action of drugs and energies used to combat disease. And it is from this standpoint, the chemical life-history of the cell, that I believe electro-therapeutics should be most carefully studied, and it is in this line of thought, that I invade that almost unknown intrapolar region and venture to suggest a speculative hypothesis which may serve as a basis for exact electrical treatment, founded upon the actual or possible chemical changes going on in disease, as in health, in living tissues, and upon the supposition, that if chemical affinity may create a potential difference, and an electro-motive force in the tissues, then external (medical) electro-motive force and electric current, may, in turn, promote, or arrest in the same tissues, that chemical affinity (nutritional) which in the first instance was capable of creating the potential difference and resulting animal current.

Living a Process of Chemical Exchanges.—Life may be said to be a chemical process. Everything that lives assimilates food, and from it forms products, most of them differing from those assimilated. The products are definite chemical products, the act of assimilation a chemical act. Oxygen, carbon, hydrogen, nitrogen, sulphur, and other elements, singly or in various chemical unions, enter a living organism, and in new combinations build it up, or become converted by chemical affinity into waste products, thrown off, as in animals, or stored up, as in plants. The cell, the structural unit of the whole, selects and appropriates to itself such of the elements as will build up its own structure, or its own cell contents, and is in time, as continuously destroyed by oxidation. The selective, appropriating, building, and destroying process, is both analytical and synthetical. In destruction or oxidation, the inspired oxygen of the air eventually unites with carbon to form carbonic acid, with hydrogen to form water, and with carbon, hydrogen, and nitrogen, to form urea, uric acid, and creatinine. By reason of these chemical exchanges, the structural entirety, and the functions of the living organism are maintained in stable equilibrium. Other familiar chemical compounds which are the results of the chemical function of living organisms are the alcohols, the organic acids, and the fats, the ammonia derivatives, such as the amides and the amines and the proteids, albuminoids, pigments, ferments, carbohydrates, and glucosides. In short, a human body is a most active chemical laboratory, whose processes and products cannot yet be imitated by the chemist.
